Consider first adoption by individual ranchers. The number of new farmers borrowing each year from the Bank of the Republic (BROU) for pasture development is used as a proxy for new adopters. A high proportion of adopters borrowed from the BROU to make their first investment. The BROU offered very favorable credit terms within an otherwise very restrictive financial context, and requests for BROU credits were handled rapidly. BROU credit recipients also received good technical assistance from the Plan Agropecuario (PLAN), which coordinated the livestock development project. About 15,000 different ranchers received credits between 1961 and 1976 (Jarvis 1977). The timing of their first loans is given in table 1.

The information on borrowers provides a good estimate of total adopters and, more important, the rate at which new adopters appeared over time. A few ranchers probably made their first pasture investments without borrowing from the BROU, but the BROU data are consistent with the number of adopting ranchers that appears in the 1970 Agricultural Census and in several recent sample surveys (Alonso and Perez).

By rearranging equation (1), we obtain

$$\frac{Z_t}{K - Z_t} = c^{c+\phi t}, \tag{2}$$

which, if K is known, can be estimated linearly in logarithms. Because K was not known, equation (2) was estimated by varying K parametrically from 10% to 100% of the total producers considered potential adopters (29,000).[1] The equation yielding the highest R^2 was assumed to give the best conditional estimates for K and ϕ. The best estimate suggests that the logistic curve reflects closely the adoption of improved pastures by Uruguayan ranchers (table 2). In equation (2), which is an autoregressive transformation of equation (1), R^2 is maximized at $K/T = 0.56$. This implies that 56% of Uruguayan producers will eventually adopt, with 90% of the ultimate ceiling being reached in 1975, and 99% in 1979.

These results have two implications: (*a*) a majority of potential adopters have invested in

[1] Of the 77,000 farms and ranches in the 1970 agricultural census, the BROU considered 29,000 potential borrowers. Farms with less than 10 hectares (23,000) were excluded as too small. Larger farms in areas where livestock is not produced (13,000) and farms having title or credit problems (12,000) also were excluded. The 29,000 farms considered potential borrowers control 85% of total agricultural area.

[2] The difference of beef price from its mean was used, preserving the comparability of the constant term with that in previous regressions. Price was lagged one year; decisions regarding pasture investments are usually made at the end of one year for implementation early in the next.

[a] Date when the projected percentage of ceiling is reached is given in parentheses.

improved pastures, confirming that information on pasture use and profitability is widespread; (*b*) the entry of new adopters is now small and declining. Unless some fundamental factor is altered, few additional adopters will appear.

Nonetheless, improved pasture area could expand on ranches where adoption has already occurred. In fact, it was originally expected that Uruguayan adopters would begin with small investments and steadily increase the proportion of their ranches devoted to improved pastures until a high proportion of total pasture area had been converted. Such was the experience in New Zealand under similar conditions. Some expansion of planted area has occurred on adopting ranches in Uruguay, but it is important to test if this expansion will continue.

Improved pastures, once established, can be productive indefinitely if properly managed and refertilized. Pastures of twenty years and more are common in New Zealand, but intensive pasture management requires an approach different from the extensive ranching traditionally practiced in Uruguay. Also, beef prices are not sufficiently high to make improved pastures profitable enough to induce farm intensification, as once thought possible (Hirschman). Thus, pasture deterioration in Uruguay has been more rapid than in New Zealand. Estimated at about 8% per year until 1974, Uruguayan pasture deterioration has been even higher since then, due to overgrazing and reduced refertilization during the livestock crisis which began in that year. Depreciation reduces net investment significantly below gross investment, especially since the total stock of improved pastures has grown (table 1). Although 2.8 million hectares were planted prior to 1977, only 1.3 million were still in production at that date.

Net pasture improvement is the variable of interest. Fortunately, the data on both annual investments and depreciation are good. The PLAN has monitored closely a large sample of ranches over the last fifteen years. The resulting depreciation estimates are consistent, at the national level, with data from agricultural census and subsequent sample surveys.

The cumulative net hectares of improved pasture in production were fitted to a logistic equation using the same procedure followed for ranch adopters. R^2 was maximized at a ceiling equal to 18% of the area assumed suitable for improved pastures (14 million hectares). However, serial correlation was present even after an autoregressive transformation, making the estimated coefficients statistically insignificant. Other variables, like prices, then were included in the analysis.

The Effects of Prices on Diffusion

Previous studies recognized that diffusion could be affected by variables such as prices. Griliches showed that the diffusion rate of hybrid seeds in different farming areas were positively related to the increased profit achieved by the farmers introducing the new seed. Mansfield (1961) showed that diffusion rates of various technologies in several industries were positively related to the profitability of the new technologies. I am not aware of research in which the diffusion rate of a single innovation has been expressed as a function of economic variables, although Mansfield (1968, p. 140) suggests this possibility.

Beef prices in Uruguay oscillated markedly between 1960 and 1978 (table 1). Because a return from low prices in 1975–76 to normal market conditions could encourage wider diffusion, the logistic was reformulated to estimate directly the effect of price on hectares planted.

First, only ϕ, the rate of diffusion, was made a function of beef price. Letting $\phi = \phi_0 + \phi_1 P$,[2] equation (1) becomes

$$(3) \qquad Z_t = \frac{K}{1 + e^{-c-\phi_0 t-\phi_1 Pt}}.$$

The inclusion of prices improves the results (table 2, equations [3] and [4]). The regressions were carried out with and without an autoregressive transformation; in both cases, the Durbin-Watson statistic is in the indeterminate range. The price coefficient is positive and significant at the 2% level, assuming no serial correlation. Iterating over K yielded maximized R^2 at $K/T = 0.14$. Assuming no change in the technology's profitability, 90% of the ceiling would be reached in 1975 and 99% in 1980.

An iterative nonlinear least-squares method was used next, permitting a direct estimate of K. Thus both ϕ and K are specified as functions of the beef price. This estimator is probably more efficient than the log-linear (Oliver). The specification also was slightly changed by assuming that diffusion followed a nonlogistic path until 1961, when the livestock develop-

ment project was initiated, and afterwards a logistic path (Economides). Much experimentation was required before the new pasture technology was adequately adapted to Uruguayan climate and soils. Diffusions along a logistic path probably did not begin until 1965. Slow growth between 1961–65 skews the diffusion slightly from a true logistic.

$$(4) \qquad Z_t = mT + \frac{k_0T + k_1PT}{1 + e^{-c\phi_0 - \phi_1 Pt}},$$

where $m + k_0 = K/T$.

Equation (4) was estimated for both adopting ranchers and for planted hectares with different zero restriction on the values of m, k, and ϕ_1 (table 3). M is significant at the 5% level only once for adopting ranchers but nearly each time for planted hectares. In the latter case, this formulation reduced the Durbin-Watson statistic.

When only ϕ is a function of beef price, the price coefficient is positive but not significant for either adopting ranchers or planted hectares. Price had little impact on the rate of diffusion. When only K is a function of price, the price coefficient is positive and significant at the 1% level for both adopting ranchers and planted hectares. Price had an impact on the ceiling. Correcting for slight heteroscedasticity did not affect the parameter estimates.

When both K and ϕ are functions of beef price, the results are not completely satisfactory; the functional form chosen cannot fully characterize the price effect. For adopting ranchers, neither coefficient is statistically significant; while for hectares planted, both are statistically significant. The coefficient on k_1 is positive and that on ϕ_1 is negative. The sign on ϕ_1 changes. Because the ceiling is sensitive to price and the diffusion rate is not, the increased ceiling (resulting from a price increase) must be associated with a longer diffusion period. With the formulation used, ϕ_1 must have a negative sign. This does not imply that a price increase itself causes the diffusion rate to decline.

The estimated ceilings for the two diffusion processes are quite similar for both the nonlinear and the log-linear methods. For adopting ranchers, both methods estimate a ceiling of about 0.56. For planted hectares, the nonlinear method provides the only significant estimate, about 0.115, slightly lower than the statistically insignificant estimate provided by the log-linear method. The diffusion rate estimated by the nonlinear estimator is significantly higher than that estimated by the log-linear method for hectares planted, but about the same for adopting ranchers.

All estimates suggest that diffusion will reach a ceiling well below the area the government of Uruguay believed feasible. Beef

price variation influences the number of ranchers finding the technology profitable and the amount planted by those who adopt. However, each influence appears small. The price elasticity of K/T for adopting ranchers is only about 0.05, and for planted hectares about 0.3.[3] Thus, given an estimated ceiling of 11.5% of total pasture area under mean price conditions, increasing the beef price by 10% would increase the ceiling only from 11.5% to 11.8%. Doubling the beef price would increase the ceiling only to 15%.

To study the diffusion rate further, residuals from the simple logistic, estimated by both the log-linear and the nonlinear estimators, were regressed on a series of variables. These variables included beef price in year t and year $t-1$, the fertilizer price (net of government subsidy) in year t and $t-1$, the inflation rate, and the Central Bank index used to adjust principal and interest payments on pasture improvement loans. No variable except beef price had a statistically significant coefficient.[4] A more significant coefficient was obtained when beef price was multiplied by a time trend. As more ranchers each installed more improved pastures, a higher proportion of pastures became marginally profitable and are therefore sensitive to price variation. In the period 1960–76, beef prices explain 60% of the residual variation for the nonlinear estimator. Nonetheless, the total variation about the logistic curve is small when compared with the pattern predicted by the logistic itself.

The Sensitivity of the Logistic Coefficients to Period Variation

Estimating the logistic curve for different subperiods, beginning with 1961–76 and subtracting one year at a time, permitted analysis of coefficient sensitivity to changing numbers of observations. Using the nonlinear method, reasonably similar coefficient estimates significant at the 1% level were obtained for the period 1961–71 through 1961–76. The estimates for the periods 1961–69 and 1961–70 were statistically insignificant; no estimates were sought for earlier periods.[5] It appears that an inflection point must be reached before stable coefficient estimates emerge.

The estimates of K/T for various periods vary only slightly, from 0.10 to 0.15. The highest estimate exceeds the lowest by 50%, but both are low relative to the total number of hectares considered suitable for improved pasture. Thus, estimation of the logistic curve would have indicated by 1971 that the ceiling would be low. Even during the period of favorable prices and high annual net pasture investments, 1971–73, the estimated ceiling did not increase radically. The government therefore might have gained several important years by recognizing that diffusion was to be more limited than expected. It then could have devoted more resources to studying the factors limiting diffusion and developing policies for increasing it.

Further Implications of the Price Coefficients

Cattle producers in Uruguay have experienced extreme beef price cycles during the last two decades. These cycles probably explain the low estimated price elasticity of pasture improvement. Because producers are accustomed to wide price cycles, producers' price expectations likely contain both a mean and a cyclical component. If so, producers are unaffected in their long-run investment plans by price variations which do not alter the mean price component. Relatively small adjustments are made only when a permanent change in the mean price is expected.

Even so, the effect which price variations have had on diffusion during recent years can be outlined briefly (fig. 1). In 1975, the total stock of improved pastures peaked at about 1.6 million hectares, or 11.5% of total pasture area. The planted area declined since 1975, to about 1.3 million hectares in 1978, or 9% of total pasture area. The 1975 figure reflects the impact of high prices during the period 1972–74, which raised the expected ceiling temporarily to about 13.3%. The estimated logistic function indicates, however, that diffusion had

[3] Borrower information does not permit identification of ranchers who once adopted, but subsequently dropped, pasture improvement. Hence, the measured price elasticity is probably underestimated.

[4] The coefficients on inflation and the adjustment index displayed the expected signs, assuming that inflation would reduce the real interest rate on partially adjusted loans and that an increase in the adjustment index would increase the real interest rate ranchers expected to pay.

[5] The length of the diffusion period for improved pastures in Uruguay (twenty years) is similar to those of other technologies in other situations (Mansfield 1968).

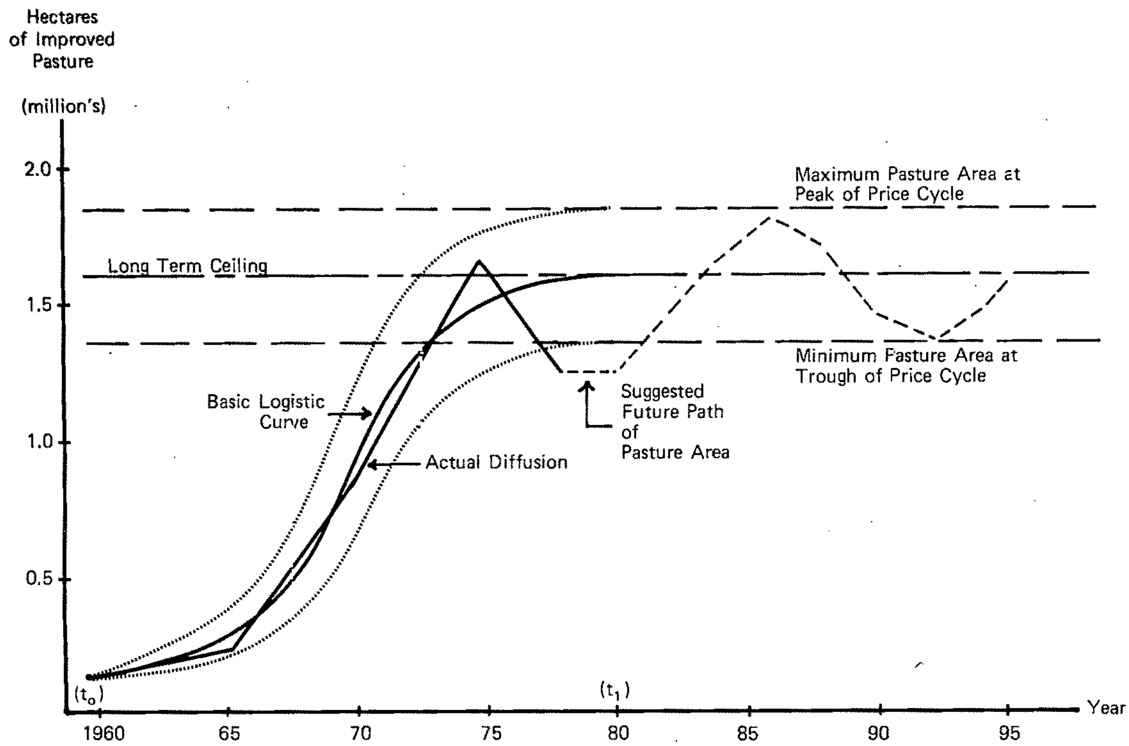

Figure 1. Stylized price response during diffusion and thereafter

not ended by 1975, having reached only about 90% of its final ceiling. Accordingly, the area planted to improved pastures should have been about 12% of total pasture area (0.9 × 13.3). This figure is close to the 11.5% actually recorded. Similarly, the low prices of 1975–77 would have lowered the ceiling to about 10.5% of total area. By 1978, however, the diffusion should have reached more than 95% of the (mean price) ceiling. Thus, the area dedicated to improved pastures would have been about 10% of total pasture area, close to that actually observed, 9%.

Assuming that prices cycle the same mean observed during the last twenty years, the area planted will average 11.5% over the price cycle. Because this ceiling already has been reached, no further permanent diffusion is expected. However, when prices rise to their peak, about 50% above the mean price, the total area planted should rise to about 13%. When prices decline to the trough, the area should decline to about 10%. However, if either international demand for Uruguayan beef or government policy determining the relation between domestic and international prices are altered, the "permanent" ceiling could be changed.

The Underlying Causes of Limited Improved Pasture Diffusion

Farm level information also was sought to explain why some producers have not adopted, and why adopters usually have planted, improved pastures on only a small proportion of their ranches. The evidence is fairly clear on two major issues (Jarvis 1980). First, about one-third of Uruguay's ranchers have not adopted because currently available fertilized grass-legume pastures do not thrive under some soil and climactic conditions. Second, improved pastures are used sparingly even on ranches where adoption has occurred because their marginal profitability declines for three reasons: (*a*) the impact of the pastures on total beef output varies by season and by the type of animal fed (under current conditions, improved pastures are profitable when planted principally to ease the winter forage shortage); (*b*) as a ranch's area of improved pastures is increased, management becomes more complex; and (*c*) after the improved area reaches about 20%–25%, forage is wasted during seasons of abundant production because existing herds cannot consume it, and it is not profitable to harvest and store it.

Technological Improvements and the Logistic Curve

Over time, refinements have been made in the availability and management of Uruguayan technology, resulting in some upward shift in improved pasture profitability. These refinements surely have extended the diffusion of improved pasture, though it is difficult to measure their effects with the data available. Unless similar but distinct technologies can be identified, we cannot determine when the ceiling for each is reached. Accordingly, the observed diffusion path will be an aggregate for a group of technologies which appear unique but are developed and introduced serially. The shape of the aggregate diffusion path will reflect the heterogeneity of soils, climate, and producers, plus the timing of new advances. In Uruguay, most of the important technological advances were made before 1966. Thus, the diffusion path probably has not yet been seriously affected. However, any major technological improvement could result in additional diffusion, which itself could be logistic in nature.

The Supply and Demand of Marketing Contracts under Risk

Steven T. Buccola

Bernoullian decision theory is used to characterize a firm's willingness to purchase or sell a good under contract. Contract supply and demand functions are then specified in which willingness to contract is related to contract-pricing provisions, to decision maker risk aversion, to open market opportunities, and to other factors. On the basis of these relations, a theory of exchange is proposed which incorporates decision making under risk. Implications of the analysis differ by contract type; cost-plus and fixed-price forward deliverable contracts are emphasized.

Key words: exchange, expected utility, forward deliverable contracts, marketing contracts, risk.

Agricultural economists have made wide use of programming techniques to generate risk-efficient farm plans and marketing portfolios (Ward and Fletcher, Anderson, Barry and Willmann, Schurle and Erven). In several studies, the additional step has been taken of employing decision maker utility functions to generate maximum-expected-utility solutions (Eidman, Dean, Carter; Attanasi and Karlinger).

A principal limitation of both approaches is that risk-efficient portfolios and their probability density functions may change dramatically as parameters of alternative farm enterprises or marketing options are varied (Buccola and French 1978). For example, new risk-efficient frontiers must be developed each time the mean return of an individual marketing or production option is revised. Any normative economic analysis requires redevelopment of optimum solutions once important parameters are varied. In neoclassical theory, entrepreneurs identify new maximum-profit output or input levels in response to each new output or input price, and these responses are incorporated into a broader theory of exchange. No such theory has been elaborated for decision makers who wish to select portfolios of exchange arrangements that maximize Bernoullian expected utility, although related work has been conducted by Holthausen, Hildreth (1974), and Buccola and French (1979).

In this paper, aspects of such a theory of exchange under risk are investigated. The analysis focuses on a buyer and seller of a fixed quantity of a single commodity, each of whom seeks to allocate his purchases (or sales) between two exchange arrangements so as to maximize his own expected utility. An example is that of a farmer who is faced at planting time with allocating his eventual product sales between forward deliverable contracts and open market transactions. A first handler may face a similar problem in allocating his eventual raw product purchases.

The Seller

Consider first a firm which plans to produce A units of a good; it has the choice of selling some of these units under marketing contract and some on the open market. The contract may take numerous forms. A wide class of marketing contract arrangements may be defined by expressing the price clause of the contract as a price base B and an associated contract price parameter k. For instance, the price received under a cost-plus arrangement would be kB, where B is the seller's per unit variable cost of production (a random variable) and $k > 1$ is some positive factor. In a fixed-price arrangement, both k and B would

be stated constants. Defining M as the open market price, V as the proportion of A sold under contract, C as per unit variable costs, and F as per unit fixed costs, the seller's profit π_s is

$$(1)\quad \pi_s = A[VkB + (1 - V)M - C - F],$$

where $0 \leq V \leq 1$.

The form of the expected utility function associated with (1) depends upon the form of the decision maker's Bernoullian utility function for profit. A variety of functional forms has been proposed. Unfortunately none of those exhibiting the desirable property of decreasing absolute risk aversion permit an expected utility formulation that can be maximized explicitly (Lin and Chang, Keeney and Raiffa).[1] This analysis is confined to the negative exponential function $U = -\exp[-\lambda\pi]$, $\lambda > 0$, with constant absolute risk-aversion coefficient λ. Freund has shown that if returns π are normally distributed, the expected utility function associated with negative exponential utility may be maximized by maximizing the certainty equivalent $Z = E(\pi) - (\lambda/2)\text{var}(\pi)$ if $\lambda > 0$.

In the following, expected values are denoted by E_i, variances by S_i^2, and covariances by S_{ij}. Assuming that the variance of fixed costs F is zero, the certainty equivalent Z of risky prospect (1) is

$$(2)\quad \begin{aligned} Z = {} & A[a + (-E_m + E_bk)V] \\ & - (\lambda/2)A^2[b + (2c + 2dk)V \\ & + (S_m^2 - 2S_{bm}k + S_b^2k^2)V^2)], \end{aligned}$$

where

$$\begin{aligned} a &= E_m - E_c - F \lesseqgtr 0, \\ b &= S_m^2 + S_c^2 - 2S_{mc} \geq 0, \\ c &= -S_m^2 + S_{mc} \gtreqless 0, \\ d &= S_{bm} - S_{bc} \gtreqless 0. \end{aligned}$$

The portfolio proportion V^* at which certainty equivalent Z reaches an extreme value is

$$(3)\quad V^* = \frac{(-E_m + E_bk) - \lambda A(c + dk)}{\lambda A(S_m^2 - 2S_{bm}k + S_b^2k^2)},$$

where $0 < V^* < 1$. Second-order conditions for a maximum are satisfied because

$$\partial^2Z/\partial V^2 = -\lambda A^2(S_m^2 - 2S_{bm}k - S_b^2k^2)$$

is nonpositive regardless of the value of k. The seller would maximize expected utility if he could sell AV^* of his product under the contract arrangement and $A(1 - V^*)$ at the open market price.

Supply of Marketing Contracts

Proportion V^* may be interpreted as the seller's willingness to sell under contract. It increases with the expected return (E_bk) and decreases with the variance of return ($S_b^2k^2$) of the contract. In addition, willingness to contract is a function of price parameter k, risk-aversion coefficient λ, and total sale quantity A. The seller's contract supply curve is the set of proportions V^* that is generated as price parameter k varies and λ and A are held fixed. The slope of this curve is a complex function of k. Better insight into the behavior of the supply curve is provided by analysis of the responsiveness of V^* to the risk-aversion parameter λ. For this purpose, it is useful to define the "equi-mean" value of price parameter k as that value which equates the expected values of the contract and market prices; that is, it is the value of k for which $E_bk = E_m$, or $k = E_m/E_b$.

If k is below equi-mean (and thus the marketing contract offers lower return than the open market), increases in the risk-aversion coefficient increase the seller's relative preference for the contract. If k is above equi-mean, increases in risk aversion decrease relative preference for the contract. At the equi-mean point, risk aversion has no impact on such preferences. To prove this, note that the partial derivative of V^*, the optimal contract share of the portfolio, with respect to λ is

$$(4)\quad \partial V^*/\partial\lambda = \frac{E_m - E_bk}{\lambda^2A(S_m^2 - 2S_{bm}k + S_b^2k^2)}.$$

Where $k < E_m/E_b$, expression (4) is positive (since the denominator is positive), meaning that V^* rises with λ. Where $k > E_m/E_b$, V^* falls with increasing λ. On the other hand, if $k = E_m/E_b$, the value of (4) is always zero.

As a consequence, increases in risk aversion cause the contract supply curve to rotate counterclockwise around the contract price parameter k's equi-mean value. That is, increasing risk aversion decreases the sensitivity with which optimal portfolios react to changes in the price parameter. The greater the positive or the smaller the negative corre-

[1] An example is the Bernoullian utility function recommended by Hildreth (1977), $U = ax - \theta\exp[-\lambda x]$ where U is utility, x is income, and $a, \theta, \lambda > 0$. If $x \sim N(\mu, \sigma^2)$, expected utility is $EU = a\mu - \theta\exp[-\lambda^2\sigma^2/2 - \lambda\mu]$, which feasibly may be maximized only with numerical techniques. The constant elasticity family of functions recommended by Tsaing poses similar problems.

lation between the contract price base and the open market price, the greater is this rotation response to risk-aversion changes. It is easily shown that increases in the total quantity A of product sold also rotate the seller's contract supply curve counterclockwise around parameter k's equi-mean value.[2]

Cost-Plus and Fixed-Price Contracts

If a cost-plus contract is envisioned, E_b in (4) is identical to E_c, the expected variable cost of production; furthermore $S_{bm} \equiv S_{cm}$, and $S_b^2 \equiv S_c^2$. In this case, (4) may be interpreted as saying that increasing risk aversion increases, has no effect on, or decreases preference for the cost-plus contract according as the expected cost-plus price E_bk falls short of, equals, or exceeds the expected market price E_m.

If the marketing contract considered is instead a fixed price per unit, the optimal contract proportion V^* assumes an especially simple form. Because the fixed price, E_bk, is a legally or morally binding price, its variance $(S_b^2k^2)$ and all covariances involving the contract price ($S_{bm}k$ and $S_{bc}k$) are zero. Hence (3) is reduced to

$$(3)' \qquad V^* = \frac{-E_m + E_bk - \lambda Ac}{\lambda AS_m^2} = 1 + \frac{-E_m + E_bk}{\lambda AS_m^2} - \frac{S_{mc}}{S_m^2}.$$

The slope of this supply function, that is the impact of a marginal increase in the fixed price on the optimal contract proportion, is

$$(5) \qquad \partial V^*/\partial(E_bk) = \frac{1}{\lambda AS_m^2},$$

which is positive and invariant with respect to the fixed price level. Similarly, the impact of increasing risk aversion on the optimally contracted proportion is

$$(4)' \qquad \partial V^*/\partial\lambda = \frac{E_m - E_bk}{\lambda^2 AS_m^2} \gtreqless 0.$$

Fixed-price contracts have received special attention in the literature because farmers frequently have the choice at planting time of forward contracting a portion of their crop for a fixed and known price; the remainder can be sold after harvest at the prevailing market price which, at planting time, is a random variable (Barry and Willmann; Eidman, Dean, Carter). Examination of (3)', (5), and (4)' provides several important insights for risk-averse farmers with exponential utility, facing normally distributed prices and costs, and considering fixed-price contracts.

(*a*) If the covariance S_{mc} between market prices and variable production costs in (3)' is near zero, the proportion of acreage optimally allocated to a fixed-price contract is less than 100% only when the fixed price is less than the expected market price.

(*b*) As the perceived variance of open market prices increases, the proportion of acreage optimally allocated to fixed-price contracts approaches 100%.

(*c*) The effect of increasingly positive association between open market prices and production costs is to increase optimal preference for open market sales. When market prices and production costs are positively associated, even extremely risk-averse farmers will prefer a combination of fixed-price and market price sales.

The Buyer

The buyer situation comparable to the above is that in which a processing firm wishes to purchase A units of a good, transform them in some way, and resell them. The buyer has the choice of dividing its acquisitions between contract and open market purchases. Defining, on a raw-product-equivalent basis, R as the per unit resale price, T as the per unit variable cost of transformation, G as the per unit fixed cost of transformation, W as the proportion of goods purchased by contract, and all other symbols as previously noted, the buyer's profit π_b may be represented as

$$(6) \quad \pi_b = A[R - WkB - (1 - W)M - T - G],$$

where $0 \leq W \leq 1$.

If prices and yields are normally distributed and the buyer has exponential profit utility with absolute risk-aversion coefficient γ, the certainty-equivalent function Y corresponding to (6) is

$$(7) \quad Y = A[j + (E_m - E_bk)W] - (\gamma/2)A^2[f + (2g + 2hk)W + (S_m^2 - 2S_{bm}k + S_b^2k^2)W^2],$$

[2] This is seen by analysis of the partial derivative $\partial V^*/\partial A = (E_m - E_bk)/\lambda A^2(S_m^2 - 2S_{bm}k + S_b^2k^2)$.

where

$$j = E_r - E_m - E_t - G \lesseqgtr 0,$$
$$f = S_r^2 + S_m^2 + S_t^2 - 2(S_{mr} + S_{rt} - S_{mt}) \geq 0,$$
$$g = -S_m^2 + S_{mr} - S_{mt} \gtreqless 0,$$
$$h = -S_{br} + S_{bm} + S_{bt} \gtreqless 0.$$

The portfolio proportion W^* at which the buyer's certainty equivalent, and thus his expected utility, reach an extreme value is

$$(8) \quad W^* = \frac{(E_m - E_bk) - \gamma A(g + hk)}{\gamma A(S_m^2 - 2S_{bm}k + S_b^2k^2)}.$$

This again represents a maximum because

$$\partial^2 Y/\partial W^2 = -\gamma A^2(S_m^2 - 2S_{bm}k + S_b^2k^2) \leq 0.$$

Demand for Marketing Contracts

Proportion W^* is the buyer's demand for purchases under contract; the relation between W^* and k is the buyer's contract demand curve. Propositions analogous to those proven for the seller can also be proven for the buyer. For example, if k is below the equi-mean point (and thus the contract price offers higher expected return than the open market), increases in risk aversion decrease the buyer's relative preference for contract purchases. If k is above equi-mean, higher risk aversion increases relative preference for contract purchases. At the equi-mean point, risk aversion has no impact on optimal portfolio preference. These relations, which are opposite in sign to those holding for sellers, are characterized by the partial of W^* with respect to risk-aversion coefficient γ:

$$(9) \; \partial W^*/\partial\gamma = \frac{-E_m + E_bk}{\gamma^2 A(S_m^2 - 2S_{bm}k + S_b^2k^2)}.$$

Equation (9) is negative, positive, or zero according as k falls short of, exceeds, or equals E_m/E_b, the equi-mean value. Thus the buyer's contract demand curve rotates clockwise around the equi-mean value E_m/E_b as absolute risk-aversion coefficient γ rises.

Fixed-Price Contracts

In the special case of a fixed-price contract, the demand curve is always negatively sloped and linear. This holds because when $S_b^2 = 0$, (8) is reduced to

$$(8)' \quad W^* = \frac{E_m - E_bk - \gamma Ag}{\gamma A S_m^2} = 1 + \frac{E_m - E_bk}{\gamma A S_m^2} - \frac{(S_{mr} - S_{mt})}{S_m^2},$$

the slope of which is

$$(10) \quad \partial W^*/\partial(E_bk) = \frac{-1}{\gamma A S_m^2} < 0,$$

a constant with respect to the initial level of fixed price E_bk. Implications of (10) are that the buyer's demand for fixed-price purchases becomes perfectly inelastic with respect to changes in the fixed price as the absolute risk-aversion coefficient, the total quantity sought for purchase, or the perceived variance of spot market prices becomes large. In (8)', covariance S_{mt} between raw product market prices and transformation costs is normally small; but the association S_{mr} between raw product and finished product market prices is often strongly positive. Under these conditions the third term in (8)' will have negative effect, so that buyers with high risk aversion will always prefer some spot market purchases. Note that when the contract price is fixed and risk-aversion coefficients of buyer and seller are identical, slopes of the supply and demand curves are equal and opposite in sign (compare [5] and [10]).[3]

Equilibrium

It is instructive to define conditions under which seller and buyer agree on the portfolio proportions they would allocate to contract transactions. Assume the two traders have equal bargaining power and identical subjective probability distributions of revenues and costs. Then the contract price parameter k_e for which trade agreement is reached is that value of k for which V^* in (3) equals W^* in (8). Equating the right-hand sides of (3) and (8), dividing each by $\alpha = \gamma/\lambda$, then cross-multiplying and cancelling terms, this is equivalent to the value of k for which

$$\gamma A[(E_m - E_bk) - \gamma A(g + hk)] = \alpha\gamma A[(-E_m + R_bk) - \lambda A(c + dk)].$$

[3] For cost-plus contracts, the slopes are approximately equal under these conditions because terms $\lambda A(c + dk)$ and $\gamma A(g + hk)$ in (3) and (8) are small relative to $(E_m - E_bk)$. In the absence of the two former terms, V^* would be identical to $-W^*$, so that $\partial V^*/\partial k$ would equal $-\partial W^*/\partial k$.

Regrouping terms, solving for equilibrium value k_e, and substituting for g, c, h, and d,

$$(11)\ k_e = \frac{E_m(1+\alpha) - \gamma A(S_{mr} - S_{mt} - S_{mc})}{E_b(1+\alpha) - \gamma A(S_{br} - S_{bt} - S_{bc})}.$$

The equilibrium parameter increases with the expected market price and with the covariances between market price and production costs (S_{mt} and S_{mc}). It decreases with increases in the covariance between raw and final product market prices (S_{mr}).

If a cost-plus contract is considered, the contract price basis B is identical to C (per unit variable cost), so that $S_{bc} \equiv S_c^2 > 0$. In many situations, furthermore, covariances $S_{br} \equiv S_{cr}$, $S_{bt} \equiv S_{ct}$, S_{mt}, and S_{mc} are near zero. Making these assumptions, (11) reduces to

$$(11)' \qquad k_e = \frac{E_m(1+\alpha) - \gamma A S_{mr}}{E_c(1+\alpha) + \gamma A S_c^2}.$$

Hence, for the frequent, but not universal, case in which raw product and finished product market prices are positively correlated ($S_{mr} > 0$), k_e is less than E_m/E_c. That is, the expected equilibrium cost-plus price, $E_c k_e$, is less than the expected market price E_m.

If a fixed-price contract is considered, B is nonstochastic and $S_{br} = S_{bt} = S_{bc} = 0$. Equation (11) then reduces, in cross-multiplied form, to

$$(11)'' \quad E_b k_e = E_m - \gamma A(S_{mr} - S_{mt} - S_{mc})/(1+\alpha).$$

The equilibrium fixed contract price, $E_b k_e$, is less than the expected market price E_m if, as would be true in many cases, the covariance S_{mr} between raw product and finished product market prices is algebraically greater than the sum $(S_{mt} + S_{mc})$ of covariances between raw product market price and production costs. In general, the equilibrium fixed price depends on the relative magnitudes S_{mr} and $(S_{mt} + S_{mc})$ as well as on α. If seller and buyer are risk neutral ($\gamma = \alpha = 0$), or if all prices and costs are uncorrelated ($S_{mr} = S_{mt} = S_{mc} = 0$), the equilibrium fixed price equals the expected market price. In the latter case, all goods are sold by fixed-price contract because V^* in (3)' and W^* in (8)' equal one.

Applications

Data drawn from contract negotiations at planting time between a California tomato processor and producers are now used to illustrate some of the above relationships.[4]

Cost-Plus

In the first application (figure 1), producer and processor each select a marketing portfolio consisting of some combination of cost-plus contracts and open market transactions. Thus, V^* represents the proportion of total acreage the tomato seller optimally allocates to cost-plus sales, and W^*, the proportion of total acreage the tomato buyer optimally allocates to cost-plus purchases. Quantities $(1 - V^*)$ and $(1 - W^*)$ represent the proportions of total acreage optimally allocated by each to market price sales or purchases. By (3) and (8), proportions V^* and W^* are functions of markup parameter k.

The first set of supply and demand curves (solid lines) in figure 1 were derived using absolute risk-aversion coefficients actually estimated from utility responses of a tomato producer and tomato processor representa-

[4] The modeled producer had 1,333 acres of tomatoes to sell on contract to a single processor, and the processor sought to purchase by contract a total of 30,000 acres of tomatoes from all growers. Because total buyer volume exceeded total seller volume, it was assumed that the buyer treated all sellers alike from the standpoint of contract negotiations. Means, variances, and covariances were estimated from historical price and cost series and from decision makers' subjective probabilities. Chi-square tests of the null hypotheses that each price and cost variable was normally distributed did not indicate any non-normality at the 5% confidence level (Buccola and French 1978).

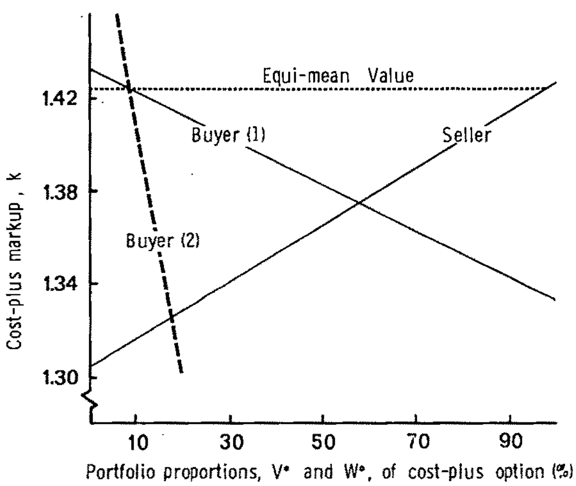

Figure 1. Equilibrium portfolio agreement between seller and buyer when the alternative marketing options are cost-plus and market price

tive. (They were $\lambda = .0012$ for the producer and $\gamma = .000045$ for the processor, where profit is expressed in \$1,000 units.) Increases in cost-plus markup k increase the proportions of total acreage offered by the producer on a cost-plus contract basis and decrease the proportions of total acreage sought by the processor on a cost-plus contract basis. Despite the complex form of functions (3) and (8), each is relatively linear in this example. Optimal portfolio proportions of buyer and seller agree only where $k = 1.374$, that is, where the cost-plus contract pays 137% of variable production costs. This is considerably below the equi-mean value (1.422) where cost-plus and market price formulas have equal expected value. The dotted line in figure 1 results when the processor-buyer's risk-aversion coefficient is increased: the demand curve rotates clockwise around equi-mean value $k = 1.422$, and the equilibrium value of k (that is k_e) falls to 1.325.

Fixed-Price

In the second application (figure 2), the producer optimally allocates a proportion V^* of his tomato acreage to fixed-price-per-ton forward deliverable contracts and the remaining proportion $(1 - V^*)$ to open market sales. The processor optimally allocates a proportion W^* of the tomato acreage he contracts to fixed-price terms and the remainder $(1 - W^*)$ to open market purchases. Because acres rather than tons are contracted in this instance, some

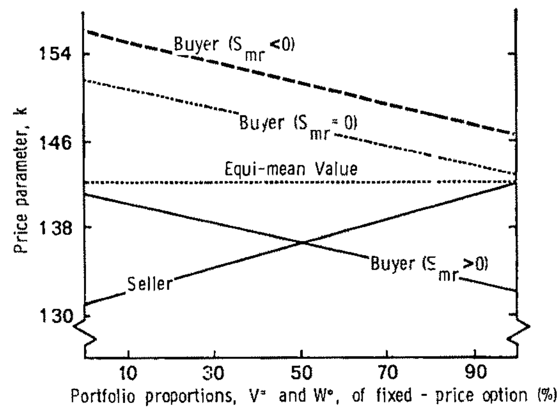

Figure 2. Equilibrium portfolio agreement between seller and buyer when the alternative marketing options are fixed price and market price

yield risk remains in the fixed-price contract, and it is not strictly true that $S_b{}^2 = S_{bm} = S_{bc} = 0$. However, the estimated coefficient of variation of tomato yields was small (less than 3%) and considered negligible for our purposes. The fixed price, represented by $E_b k$, is here varied by varying k and holding E_b constant, such that $E_m/E_b = 1.422$ (as in figure 1). Thus, a forward contract's fixed price per ton equalled the expected tomato market price per ton when k equalled 1.422.

Three situations are depicted in figure 2. In the first (solid lines), the covariance between market prices of raw tomatoes and processed tomato products (S_{mr}) was as empirically estimated. Because this covariance was positive (correlation = .514) and greater than covariance sum ($S_{mt} + S_{mc}$) in (11)′, the equilibrium fixed-price level $E_b k_e$ was less than expected market value E_m. In the second situation, covariance S_{mr} was set at zero, with the result that the processor-buyer's demand curve, equation (8)′, shifted to the right. Quantity $\gamma A(S_{mt} + S_{mc})$ in (11)′ was a relatively small number in this example; thus, in the new equilibrium solution the fixed tomato price approximately equalled the expected market value of tomatoes. For the third situation, covariance S_{mr} was assigned an arbitrary negative value (correlation = −.179), the buyer demand curve shifted further to the right, and no equilibrium solution was achieved. Further buyer-seller negotiations would, if conducted on an equal-market-power basis, result in a fixed price somewhere above the expected market value.

Conclusions

Explicit representation of decision makers' expected utility functions provides important insights into rational marketing portfolio selection. In general, a decision maker's demand for each marketing alternative is a function of the contract price parameters specified. Quantities that sellers wish to trade under each alternative may be expressed as positively sloped contract supply curves. Quantities that buyers wish to trade may be expressed as negatively sloped contract demand curves. Mutually agreeable marketing portfolios then can be determined using standard equilibrium methods.

The analysis shows that, among individuals with exponential utility, sensitivity of optimal marketing portfolios to changes in contract price parameters diminishes as risk aversion rises. Negotiated equilibrium levels of such parameters as cost-plus markups or fixed prices depend critically upon perceived covariances between revenue and cost variables in buyers' and sellers' profit functions. Only in special cases, such as when decision makers are risk neutral or covariances are zero, could one anticipate that all negotiated price formulas would have equal expected values.

An important application of this analysis to farmer market contracting is where farmers are faced with the choice at planting time between sales at fixed-price, forward deliverable contracts and sales at eventual open market prices. An example suggests that mutually agreeable fixed prices for forward deliverable contracts are highly sensitive to the covariance that (*a*) the buyer perceives between raw product and finished product prices, and (*b*) the seller perceives between raw product prices and farm production costs. Other than by reference to these covariances, and to the risk aversion of the buyer relative to the seller, it is impossible to determine whether fixed prices negotiated on an equal-market-power basis will be above, equal to, or below expected market prices.

The present framework does not permit sellers and buyers to select the stage in the production process at which it would be optimal to contract. However, given its static limitations, the framework is applicable to a wide variety of pricing arrangements between sellers and buyers, including use of futures contracts. Its principal value is to extend the theory of exchange to cases in which the outcomes of marketing arrangements are not known with certainty.

An Interval Approach to Measuring Decision Maker Preferences

Robert P. King and Lindon J. Robison

A method for constructing interval measurements of decision makers' absolute risk-aversion functions is presented. Under this new procedure, the form of the absolute risk-aversion function is not restricted, and the precision of the interval measurement can be determined by the analyst. Interval measurements are used with the criterion of stochastic dominance with respect to a function to order uncertain choices. An empirical test shows that interval measurements exclude preferred choices from consideration less often than do single-valued utility functions and are more discriminating than first- and second-degree stochastic dominance.

Key words: preference measurement, risk aversion, stochastic dominance, uncertainty.

Agricultural producers operate in a highly uncertain decision-making environment. Recognizing this, agricultural economists have made considerable progress in incorporating uncertainty into the framework for decision analysis (e.g., Halter and Dean; Dillon; Anderson, Dillon, Hardaker). These advances often have proved difficult to implement in practice, however, and in many instances the impact of uncertainty is either ignored or treated in a manner that is difficult to reconcile with theory.

The expected-utility hypothesis is the basis for much of the theory of decision making under uncertainty. It states that choices made under uncertainty are affected by the decision maker's preferences and expectations, and it provides a general decision rule—expected utility maximization—which integrates information on these two factors to identify preferred choices. Despite its wide acceptance as a theoretical tool, important operational problems make the expected-utility hypothesis difficult to apply in the analysis of actual decisions. One such problem is that use of the expected-utility hypothesis requires explicit information about the decision maker's preferences. Unfortunately, as Young et al. note, preferences are difficult to measure accurately enough to permit the reliable evaluation of alternative choices.

In this paper, a new method for measuring preferences is introduced. This method overcomes many of the problems stemming from the use of existing procedures and can be a useful tool in applied decision analyses. In the sections which follow, currently used techniques for measuring and representing preferences are first reviewed. A recently developed criterion for ordering uncertain choices, stochastic dominance with respect to a function (Meyer 1977a), is then introduced, and a preference measurement technique designed to be used in conjunction with this criterion is presented. Procedures for implementing this new method are then described, and the results of an empirical test of its effectiveness are presented.

Existing Techniques for Measuring and Representing Preferences

The most direct way to measure preferences is to derive the decision maker's utility function. Utility functions relate the outcomes of choices to single-valued indices of desirability. As such, they are exact representations of preferences. Because of shortcomings in the design of preference elicitation interviews (Officer and Halter, Binswanger), problems in

statistical estimation (Knowles), and respondents' own lack of precise knowledge about their preferences (Zadeh), however, utility functions also tend to be unreliable. Despite such problems, a utility function, once estimated, is usually treated as an exact representation of preferences when alternative choices are ordered. Any absolute difference in the expected utilities of two choices is taken as a clear indication that one is preferred to the other. As a result, inaccuracies in an elicited utility function can cause the rejection of a choice actually preferred by the decision maker.

Imprecision in the measurement of decision maker preferences can be recognized explicitly be using an efficiency criterion rather than a single-valued utility function to order alternatives. An efficiency criterion is a decision rule that provides a partial ordering of choices for decision makers whose preferences conform to a specified set of conditions. For example, first- and second-degree stochastic dominance (Hadar and Russell; Hanoch and Levy) are among the simplest efficiency criteria. First-degree stochastic dominance holds for all decision makers who prefer more to less—i.e., for all those who have positive marginal utility for the performance measure being considered. Second-degree stochastic dominance places an additional restriction on preferences. It requires that the decision maker's marginal utility be both positive and decreasing. Other familiar efficiency criteria, such as mean-variance efficiency (Markowitz) and mean-absolute deviation efficiency (Hazell), impose alternative sets of restrictions on preferences and/or on the form of the probability distributions of the performance measure.

The use of an efficiency criterion to order choices is, in many respects, preferable to the use of a single-valued utility function. No direct preference measurements need be made, and, if enough alternatives can be eliminated, a final choice can be made by direct comparison of the outcome distributions of those that remain. Unfortunately, the most commonly used efficiency criteria have several serious shortcomings which limit their usefulness. First, they often are not discriminating enough. In an application of second-degree stochastic dominance by Anderson, for example, twenty of forty-eight randomly generated farm plans were in the efficient set. Furthermore, the restrictions on preferences imposed by an efficiency criterion may be difficult to reconcile with theoretical and empirical findings. Again focusing attention on second-degree stochastic dominance, strong theoretical arguments have been made for the possibility of increasing marginal utility over certain outcome ranges (Friedman and Savage; Kahneman and Tversky), and empirical evidence indicates that agricultural producers do at times exhibit increasing marginal utility (Officer and Halter; Conklin, Baquet, Halter; Dillon and Scandizzo; Halter and Mason). Finally, unrealistic assumptions also may be imposed on probability distributions. Under mean-variance efficiency, perhaps the most widely used efficiency criterion in the agricultural economics literature, outcome distributions are assumed to be normal. This assumption is highly suspect, given the skewed nature of price and yield distributions in agriculture.

There is a need, then, for efficiency criteria which are both more flexible and more discriminating than those described above. Furthermore, there is a need for preference measurement techniques which, though less precise than those used to construct single-valued utility functions, provide an empirically based representation of a decision maker's preferences. In the two sections which follow, a more powerful efficiency criterion, stochastic dominance with respect to a function (Meyer 1977a), is introduced, and a preference measurement technique designed to be used in conjunction with this criterion is presented.

Stochastic Dominance with Respect to a Function

Stochastic dominance with respect to a function is an evaluative criterion which orders uncertain choices for decision makers whose absolute risk-aversion functions lie within specified lower and upper bounds. The absolute risk-aversion function (Arrow, Pratt), $r(y)$, is defined by the expression:

$$r(y) = -u''(y)/u'(y), \tag{1}$$

where $u'(y)$ and $u''(y)$ are the first and second derivatives of a von Neumann-Morgenstern utility function $u(y)$. In the most abstract terms, values of the absolute risk-aversion function are simply local measures of the degree of concavity or convexity of a utility function. As such, they also serve as indicators of the extent to which a decision maker

is risk-averse or risk-loving. Perhaps the most important property of the absolute risk-aversion function, however, is that it is a unique measure of preferences, while a utility function is unique only to a positive linear transformation.[1] In effect, then, upper and lower bounds on a decision maker's absolute risk-aversion function define an interval representation of preferences. Stochastic dominance with respect to a function orders choices on the basis of such a representation.

More formally stated, stochastic dominance with respect to a function is a criterion which establishes necessary and sufficient conditions for the distribution of outcomes defined by the cumulative distribution function $F(y)$ to be preferred to that defined by the cumulative distribution function $G(y)$ by all individuals whose absolute risk-aversion functions lie everywhere between lower and upper bounds $r_1(y)$ and $r_2(y)$. As developed by Meyer (1977a), the solution procedure requires the identification of a utility function $u_0(y)$ which minimizes

$$\int_{-\infty}^{\infty} [G(y) - F(y)]u'(y)dy, \tag{2}$$

subject to the constraint,

$$r_1(y) \leq -u''(y)/u'(y) \leq r_2(y), \tag{3}$$

for all y. The expression in equation (2) is equal to the difference between the expected utilities of outcome distributions $F(y)$ and $G(y)$. If, for a given class of decision makers, the minimum of this difference is positive, $F(y)$ is unanimously preferred to $G(y)$, since this implies that the expected utility of $F(y)$ is always greater than that of $G(y)$. If the minimum is zero, it is possible for an individual in the relevant class of decision makers to be indifferent between the two alternatives, and they cannot be ordered. Should the minimum be negative, $F(y)$ cannot be said to be unanimously preferred to $G(y)$. In this case, the expression

$$\int_{-\infty}^{\infty} [F(y) - G(y)]u'(y)dy \tag{4}$$

must then be minimized subject to equation (3) to determine whether $G(y)$ is unanimously preferred to $F(y)$. It should be noted that a complete ordering is not ensured by the criterion. It is possible for the minimum of both equations (2) and (4) to be negative, which implies that neither distribution is unanimously preferred by the class of decision makers being considered.

Meyer uses optimal control techniques to derive the necessary and sufficient conditions for the solution of this problem. These conditions define a rule for determining the absolute risk-aversion function of the utility function which minimizes equation (2)—a rule can be applied if the relatively unrestrictive assumption that $[G(y) - F(y)]$ changes sign a finite number of times is met. Details of the solution technique are given in Meyer (1977a), and an example showing how the solution can be implemented is given in King and Robison (1981).

The major advantage of this criterion is that it imposes no restrictions on the width or shape of the relevant risk-aversion interval. The lower and upper bound absolute risk-aversion functions need not be constants and can be placed anywhere in risk-aversion space. Less flexible efficiency criteria, such as first- and second-degree stochastic dominance, can be viewed as special cases of this more general criterion. The requirement under first-degree stochastic dominance that marginal utility be positive places no restrictions on the decision maker's absolute risk-aversion function—i.e., $r_1(y) = -\infty$ and $r_2(y) = \infty$ for all possible values of y. The requirement under second degree stochastic dominance that marginal utility be decreasing as well as positive, on the other hand, implies that $r_1(y) = 0$ and $r_2(y) = \infty$ for all values of y.

A simple example will help to demonstrate the advantages of stochastic dominance with respect to a function. Consider the three outcome distributions in table 1. Let them represent probability distributions of net farm income levels associated with three distinct,

Table 1. Probability Distributions of Net Farm Income for Three Hypothetical Farm Plans

A	B	C
	($)	
9,950[a]	10,000	10,100
12,000	12,000	10,100
13,075	13,000	10,100

[a] Each element of each distribution has a one-third probability of occurring.

[1] Because a utility function is unique only to a positive linear transformation, $u(y)$ and

$$u^*(y) = a + bu(y), b > 0$$

are strategically equivalent, though perhaps highly dissimilar, utility functions. The absolute risk-aversion functions of these two utility functions, however, are identical.

hypothetical farm plans. Assume that a single-valued utility function of the following form has been elicited for an agricultural producer:

$$u(y) = -e^{-.0003y}, \tag{5}$$

where y is net farm income and .0003 is an estimated constant value of the decision maker's absolute risk-aversion function. This value falls within the range suggested by Freund. Using this utility function and the criterion of expected utility maximization to order the three farm plans, B is preferred to A, and both A and B are preferred to C. The difference in the expected utilities of plans A and B is quite small, however. Most decision makers would have difficulty choosing between them in an actual decision situation, and many would ask for additional information before selecting one over the other. With strict reliance on the ordering provided by equation (5), however, only plan B would be presented to the decision maker.

Plans A and B cannot be ordered under the criteria of first- and second-degree stochastic dominance. The difficulty decision makers would have in ranking these distributions is recognized, then, under these criteria. Unfortunately, they also fail to order distribution C with respect to either A or B. This is true because the ultimate risk averter, the decision maker who employs a maximin decision rule and so prefers distribution C, is included in the class of decision makers for whom both first and second degree stochastic dominance hold. As a result, nothing is eliminated from consideration.

Finally, if these three distributions are evaluated using stochastic dominance with respect to a function with lower and upper bounds on absolute risk aversion being set at .0001 and .0004, only plans A and B are in the efficient set. Unlike the single-valued utility function, then, this criterion does not require an exact representation of preferences and does not limit the efficient set to a single choice when the ordering of some alternatives may be sensitive to small errors in the measurement of preferences. Unlike other first- and second-degree stochastic dominance, it does not require that fixed restrictions be imposed on the representation of preferences. Rather, because the bounds on absolute risk aversion can be placed anywhere in absolute risk-aversion space and as close together as desired, stochastic dominance with respect to a function can be the basis for a more complete ordering than can be obtained with these criteria.

The problems associated with single-valued utility functions and first- and second-degree stochastic dominance are not particularly serious when only a few choices are involved, as is the case in this example. In situations where the number of possible actions is quite large and some optimization procedure is used to evaluate them, as is typical in farm-planning problems, these shortcomings do become important. In such an analysis one must question the wisdom of presenting the decision maker with a single optimal plan based on unreliable preference measurements, and one must question the value of presenting him with an efficient set of choices containing a very large number of plans. Stochastic dominance with respect to a function has the potential for alleviating these difficulties by allowing the analyst to specify the degree of precision with which preferences are represented.

An Interval Approach to the Measurement of Decision Maker Preferences

Stochastic dominance with respect to a function is a powerful analytical tool. If it is to be used in an applied context, however, an operational procedure for the determination of lower and upper bounds on a decision maker's absolute risk-aversion function is required. Such a procedure is introduced in this section. It uses information revealed by a series of choices between carefully selected distributions to establish lower and upper bounds on an individual's absolute risk-aversion function. The degree of precision with which preferences are measured—i.e., the size of the interval between the lower and upper bound functions—can be specified directly in accordance with the characteristics of the problem under consideration. At one extreme, the interval can be of infinite width; at the other extreme, it can converge to a single line.

The procedure for constructing interval measurements of decision maker preferences is based on the premise that under certain conditions, a choice between two distributions defined over a relatively narrow range of outcome levels divides absolute risk-aversion space over that range into two regions: one consistent with the choice and one inconsistent with it. The properties of the two distribu-

tions determine the level of absolute risk aversion at which the division is made and so define the two regions. The decision maker's preferences, as revealed by his ordering of the two distributions, determine into which of the two regions his level of absolute risk aversion is said to fall. By confronting the decision maker with a series of choices between carefully selected pairs of distributions, the region of absolute risk-aversion space consistent with the decision maker's preferences can repeatedly be divided. With each choice, a portion of that region is shown to be inconsistent with the decision maker's preferences, and the interval measurement for the level of absolute risk aversion is narrowed. The procedure continues until a desired level of accuracy is attained.

The validity of the premise that a choice between two distributions is, under certain conditions, the basis for a division of absolute risk-aversion space into regions consistent and inconsistent with a decision maker's revealed preferences can be demonstrated using a theorem proved by Meyer (1977b, p. 483). The theorem states that, given cumulative distribution functions $F(y)$ and $G(y)$, $F(y)$ is preferred to $G(y)$ by all decision makers more risk-averse than the utility function $k(y)$, and decision makers having utility function $k(y)$ are indifferent between the two distributions only if $G(y)$ is preferred to $F(y)$ by decision makers less risk-averse than $k(y)$.[2] The function $k(y)$, then, can be called a boundary function because it separates a class of decision makers who prefer $F(y)$ from a class who prefer $G(y)$.

If the distributions $F(y)$ and $G(y)$ are defined over a narrow range of outcome levels, and if the decision maker's absolute risk-aversion function can be approximated by a constant value λ over that range, preference for $F(y)$ implies that λ is greater than or equal to the minimum value of the absolute risk aversion associated with $k(y)$. Otherwise, the decision maker would be less risk-averse than $k(y)$, and his choice would be inconsistent with expected utility maximization. Preference for $G(y)$, on the other hand, implies that λ is less than or equal to the maximum value of the absolute risk-aversion function associated with $k(y)$, since $F(y)$ is preferred by all decision makers more risk-averse than $k(y)$. It should be noted that the assumption that a decision maker's absolute risk-aversion function can be adequately approximated by a constant value over a narrow range of outcome levels is critical here. The theorem stated above does not imply that decision makers who prefer $F(y)$ to $G(y)$ are more risk-averse than $k(y)$; nor does it imply that decision makers who prefer $G(y)$ to $F(y)$ are less risk-averse than $k(y)$. With the assumption of constant absolute risk aversion in the neighborhood of a given outcome level, however it can be inferred that decision makers who prefer $F(y)$ to $G(y)$ are not less risk-averse than $k(y)$, and those who prefer $G(y)$ to $F(y)$ are not more risk-averse than $k(y)$.

Boundary functions do not exist for each pair of distributions. For example, one would not exist if one distribution dominates the other by first-degree stochastic dominance. Similarly, the existence of one boundary function does not preclude the existence of others. In general, however, the properties of a boundary function for two distributions are determined by the distributions. By careful selection of distributions, a boundary function can be placed anywhere in risk-aversion space. A series of comparisons can be devised, then, which focuses successively on different regions of absolute risk-aversion space and so allows the repeated reduction of the range of risk-aversion levels consistent with the revealed preferences of a decision maker.

An example will help to illustrate how the procedure works. Consider the three outcome distributions given in figure 1. Each contains

1. Compare distributions 1 and 2, and indicate which one you prefer. If you prefer distribution 1, go to question 3; otherwise, go to question 2. __
2. Compare distributions 1 and 3, and indicate which one you prefer. __
3. Compare distributions 2 and 3, and indicate which one you prefer. __

DISTRIBUTIONS

1[a]	2	3
2,100	1,000	1,750
2,400	2,050	1,950
2,550	2,650	2,500
3,100	3,800	2,750
3,250	3,900	3,950
3,450	5,200	4,000

[a] Each element of each distribution has a one-sixth probability of occurring.

Figure 1. A sample questionnaire for interval preference measurement

[2] Using Pratt's definition of risk aversion in the large, a decision maker with utility function $u(y)$ is more (less) risk-averse than $k(y)$ if the absolute risk-aversion function associated with $u(y)$ is everywhere greater (less) than that associated with $k(y)$.

six possible outcomes said to have equal probability of occurring. Using stochastic efficiency criteria developed by Meyer (1977b), it can be shown that distribution 1 is preferred to distribution 2 by all decision makers whose level of absolute risk aversion is greater than .0005 over the range of outcome levels covered by these two distributions. Distribution 2, on the other hand, is preferred by all decision makers whose level of absolute risk aversion is less than .0001.[3] The two distributions cannot be ordered by unanimous preference over the interval (.0001, .0005), which can be termed a boundary interval in risk-aversion space. The absolute risk-aversion function associated with a boundary function for these two distributions lies everywhere within this interval over the range of outcome levels being considered. If a decision maker prefers distribution 1 to distribution 2, and if it is reasonable to assume that his absolute risk-aversion function can be adequately approximated by a constant value over the range of outcome levels covered by these distributions, it can be concluded that his level of absolute risk aversion over that range is not less than .0001, since there is unanimous preference for distribution 2 by decision makers less risk-averse than .0001. Similarly, if he prefers distribution 2, it can be concluded that his level of absolute risk aversion is not greater than .0005. Therefore, preference for either one of the two distributions identifies a portion of risk-aversion space inconsistent with the choice made.

Boundary intervals also can be identified for distributions 1 and 3 and distributions 2 and 3. For distributions 1 and 3, the interval is (−.0001, .0001), with distribution 3 preferred below the boundary interval and distribution 1 preferred above it. For distributions 2 and 3, the interval is (.0005, .0010), with distribution 2 preferred below and distribution 3 preferred above.

Using this information as a guide, the series of questions at the top of figure 1 was specified. The decision maker is always asked to make the first comparison, but which of the second two he makes will depend on the choice he makes in the first. For example, if distribution 2 is preferred to distribution 1 in the first comparison, this implies that the decision maker's level of absolute risk aversion is less than .0005. He is then directed to compare distributions 1 and 3. If he prefers distribution 1, his level of absolute risk aversion is shown to be greater than −.0001. This combined with the information from the first comparison indicates that his level of absolute risk aversion lies on the interval (−.0001, .0005). Had he preferred distribution 3, his level of absolute risk aversion would have been shown to be less than .0001, which, when combined with the information from the first question indicates that it lies on the interval (−∞, .0001). Note that, given preference for distribution 1 in the first comparison, the third comparison would not provide any new information. It could serve as a consistency check, however, since preference for distribution 3 in this case would not be consistent with preference for distribution 1 in the first question.

By making interval measurements in the neighborhood of several outcome levels and interpolating between known values, lower- and upper-bound absolute risk-aversion functions can be constructed for a much wider range of outcomes. Each of the two absolute risk-aversion intervals shown in figure 2 was based on four such measurements. In this instance, net income was the performance variable, and possible values ranged from a loss of \$5,000 to a gain of \$30,000. It should be noted that the form of absolute risk-aversion functions based on interval measurements is not restricted. For decision maker A, the bounded interval slopes downward as income increases, while for decision maker B, it slopes upward and then downward. The interval measurements for both decision makers con-

[3] Meyer (1977b) shows that distribution $F(y)$ is preferred to $G(y)$ by all decision makers more risk-averse than $k(y)$ if

$$\int_{-\infty}^{y} [G(x) - F(x)]k'(x)dx \geq 0$$

for all y, and if the inequality is strict for some value of y, and that $G(y)$ is preferred to $F(y)$ by all decision makers less risk-averse than $k(y)$ if

$$\int_{y}^{\infty} [G(x) - F(x)k'(x)dx \leq 0$$

for all y, and if the inequality is strict for some value of y. In this instance $k(y)$ takes the negative exponential form, $-e^{-\lambda y}$, where λ is a constant level of absolute risk aversion. Let $F(y)$ and $G(y)$ be the cumulative distribution functions of distributions 1 and 2, respectively. Since

$$\int_{-\infty}^{y} [G(x) - F(x)][.0005e^{-.0005x}]dx \geq 0$$

for all y, and

$$\int_{y}^{\infty} [G(x) - F(x)][.0001e^{-.0001x}]dx \leq 0$$

for all y, with the inequality being strict for some y in each case, it can be concluded that distribution 1 is preferred by all decision makers more risk-averse than .0005 and that distribution 2 is preferred by those less risk-averse than .0001.

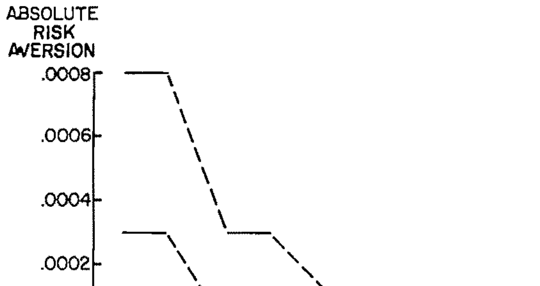

Figure 2. Interval measurements of absolute risk aversion for two decision makers

tain negative as well as positive values at some income levels. When absolute risk-aversion functions are derived from empirically estimated utility functions, on the other hand, their properties are severely limited by the functional form used to estimate the utility function (Lin and Chang). It should also be noted that the interval approach to the measurement of preferences avoids another common problem encountered in the estimation of single-valued utility functions. Because all questions posed require a choice between two uncertain prospects, biases due to preference for or aversion to gambling per se (Officer and Halter) are avoided. The greatest strength of the procedure, however, is its flexibility, which allows direct specification of the degree of precision with which preferences are measured.

Implementation of the Procedure

The discussion in the preceding section presents a method for constructing interval preference measurements, but it does not explain the mechanics of implementing this procedure. The implementation of the interval approach to preference measurement is outlined briefly in this section. A more detailed explanation is given in King and Robison (1981) along with listings of computer programs used in constructing preference measurement questionnaires and in ordering choices with the criterion of stochastic dominance with respect to a function.

Implementation of the interval approach begins with the specification of a measurement scale—a set of reference levels in absolute risk-aversion space which serve as the basis for preference measurements. Because this scale determines the degree of precision with which preference measurements can be made, careful attention should be given to its specification.

The number of reference levels on the measurement scale depends on the number of comparisons the decision maker will be asked to make as absolute risk aversion is measured in the neighborhood of any particular outcome level. As the number of choices increases, more accurate measurements can be made, but more reference levels are required. In general, if N comparisons are to be made, the measurement scale should be comprised of at least 2^N reference levels. In the example presented in the preceding section, for example, the decision maker was required to make two comparisons and the measurement scale was comprised of four absolute risk-aversion levels: $-.0001$, .0001, .0005, and .0010.

Reference levels need not be placed at regular intervals. In many instances it is desirable to concentrate them in that region of absolute risk-aversion space where the decision maker's actual level is expected to fall or in a region where relatively small changes in absolute risk aversion have a great impact on preference orderings. Experience to date indicates that most of the levels on the measurement scale should be concentrated in the risk-aversion interval between $-.0001$ and .0010. Actual measurements for a number of individuals have tended to fall most frequently within this interval, and tests on several empirical decision problems have indicated that choices are most strongly affected by changes in absolute risk aversion within this range.

Next, sample distributions must be generated, and boundary intervals on the measurement scale must be identified for as many pairs of distributions as possible. Sample distribu-

tions are constructed in a random manner by generating several hundred variates from a user-specified distribution and grouping them into sets containing an equal number of observations. Each set of observations is considered to be a distribution of outcomes, and each element of a distribution is said to have an equal probability of occurrence. The sample distributions should be defined over a relatively narrow range of outcome levels, because the decision maker's level of absolute risk aversion is said to be constant over that range. Experience to date indicates that a range of 5% to 10% of the possible range of outcomes is adequate. In past applications, six elements have been included in each distribution. More complex distributions would make decision makers' choices unduly difficult, while distributions with fewer elements may not be rich enough to make the choices interesting. The use of six element distributions also facilitates explanation of the choice situation to the decision maker, because the probability of any one element occurring can be equated directly to the probability of obtaining a specified number of dots on a single roll of a die. Distributions with either a larger or smaller number of elements can, however, be employed.

Given the measurement scale, the program that generates the sample distributions uses the criteria developed by Meyer (1977b) for stochastic dominance given lower or upper bounds on absolute risk aversion to identify the narrowest boundary interval for each pair of distributions. Absolute risk-aversion intervals defined by adjacent reference levels on the measurement scale are tested iteratively for each pair of distributions to identify the highest reference level, λ_1, such that all decision makers less risk-averse than λ_1 prefer one distribution and the lowest reference level, λ_2, such that all decision makers more risk-averse than λ_2 prefer the other distribution. These two reference levels define the boundary interval (λ_1, λ_2) for that pair of distributions.

If enough sample distributions are considered, at least one pair of distributions having a boundary interval between any two adjacent levels on the measurement scale should be identified. Once this has been done, a series of comparisons can be formulated, with each focusing on a different boundary interval. The comparisons are arranged so that the decision maker is directed through a hierarchy of choices designed to increase continually the precision of the interval measurement. In general, each comparison should focus on an interval in the center of the region of absolute risk-aversion space consistent with the decision maker's prior choices.

Series of choices among distributions centered around several outcome levels are required for the construction of an overall interval measurement. Experience to date has shown that direct measurements in the neighborhood of three or four outcome levels provide an adequate basis for the construction of lower and upper bound absolute risk-aversion functions over even a broad range of outcomes. If, for example, annual income is the performance measure for which preference information is to be elicited and the relevant income range is from 0 to \$20,000, direct measurements of absolute risk aversion could be made in the neighborhood of \$3,000, \$10,000, and \$17,000. Portions of the lower and upper bound functions based on direct measurements are connected by linear segments to determine absolute risk-aversion levels at intermediate outcome levels.

The elicitation of preferences under the interval approach is straightforward. Completion of a questionnaire comprised of four series of three comparisons takes approximately twenty minutes and requires little supervision. Experience to date has shown that decision makers find this procedure more interesting and more informative than the interview process required to elicit a single-valued utility function.

Finally, interval preference measurements are used in combination with the evaluative criterion of stochastic dominance with respect to a function to order choices. Lower and upper bound absolute risk-aversion levels for each of the outcome levels where direct measurements have been made and the outcome distributions to be ordered serve as inputs to the computer program designed to accomplish this task. A listing of that program is given in King and Robison (1981) along with a discussion of its structure and use.

An Empirical Test

A simple experiment was designed and conducted to test the effectiveness of the interval approach to the measurement of decision maker preferences. Three questionnaires were administered to a group of graduate students from the Department of Agricultural Economics at Michigan State University. The first

questionnaire employed the procedure described in the preceding sections to obtain an interval measurement of each subject's absolute risk-aversion function. The second questionnaire was used to elicit information required for the construction of a single-valued utility function for each subject. Finally, in the third questionnaire the respondents were asked to make a series of six choices between pairs of distributions, defined on the overall interval for which preferences had been measured. Information from each of the first two questionnaires was used to predict the choices made in the third questionnaire, and these predictions were compared to the actual responses. In this way the accuracy of each of the two approaches to preference measurement was tested. The distributions on the third questionnaire also were ordered by first- and second-degree stochastic dominance, so the performance of these criteria could also be evaluated.

In evaluating each approach, two criteria were considered: the number of correct predictions and the number of choices for which a definite ordering was made. A prediction was said to be correct if the respondent's choice was not excluded from the efficient set of choices and incorrect if it was excluded. The preference measure having the highest proportion of correct predictions was said to be the most accurate according to this criterion. Concern with the proportion of correct predictions is analogous to concern with the probability of Type I error in a statistical test—i.e., with the probability that a true statement will be judged false and rejected. This measure of accuracy, however, is not a good indicator of the discriminatory power of a preference measurement. First-degree stochastic dominance, which holds for all decision makers who prefer more of the performance measure to less, should never exclude a preferred choice from the efficient set and so should be perfectly accurate according to this criterion. Often, however, it also fails to exclude many choices from the efficient set. A single-valued utility function, on the other hand, is the basis for a complete ordering of choices—i.e., it always leads to an efficient set having a single element. Therefore, the number of choices actually ordered was also considered. Concern wth the discriminatory power of a criterion is analogous to concern with the probability of Type II error in a statistical test—i.e., with the probability that a false statement will be judged to be true and not rejected.

Clearly there are trade-offs between the accuracy and discriminatory power of a preference measurement. Unlike other measurement techniques and evaluative criteria, the combined use of interval preference measurements and stochastic dominance with respect to a function permits explicit consideration of these trade-offs. As the precision of the interval measurement increases, it becomes a more discriminating basis for the ordering of choices, but the probability of excluding preferred choices from the efficient set also increases. Such trade-offs between accuracy and discriminatory power were analyzed in the experimental test of the interval approach to the measurement of preferences. Direct interval measurements were made at three levels of income—the relevant performance measure in this instance. These measurements were based on a sequence of four questions at each income level. By constructing interval measurements on the basis of information available at the end of each question, however, four preference measurements—each more precise than the one which preceded it—were made for each subject.

Nine of ten subjects correctly completed all three questionaires.[4] Because each subject made six choices on the third questionnaire, each preference measurement was used to predict a total of fifty-four choices. The results of the experiment are presented in table 2. They show a clear trade-off between accuracy and discriminatory power. First-degree stochastic dominance and the single-valued utility function are at opposite extremes in this trade-off relationship, and the interval measurements are arrayed between the two. Several factors should be noted. With regard to the accuracy of the interval measurements, it falls at a relatively constant rate as the number of questions posed increases, but even at the higher levels of precision it exceeds that of the single-valued utility function. The discriminatory power of the interval measurements, on the other hand, increases dramatically as the number of questions asked at each income level increases. In contrast, first- and second-degree stochastic dominance clearly do not

[4] The tenth subject made comparisons out of order on the interval measurement questionnaire and made several inconsistent choices. The suggested format of the questionnaire has since been revised to reduce the possibility that comparisons will be made out of order. The problem of inconsistent choices, which has also occurred in other trials of the procedure, suggests that it may be desirable to incorporate consistency checks into the questionnaire. To date the value of such checks has not been formally evaluated.

Table 2. Performance Indicators for Alternative Preference Measures

Performance Indicator	Interval Measurement: Number of Questions 1	2	3	4	Single-Valued Utility Function	First-Degree Stochastic Dominance	Second-Degree Stochastic Dominance
1. Percentage of choices predicted correctly	98	88	78	72	65	100	98
2. Percentage of choices ordered	9	50	83	91	100	0	7

discriminate well among the distributions the subjects in the experiment were asked to order.

Concluding Remarks

These experimental results demonstrate how interval preference measurements allow explicit consideration of trade-offs between accuracy and discriminatory power of preference measurements. Unlike single-valued utility functions, they are not exact representations of preferences and so are not as likely to eliminate a preferred choice from consideration. Unlike the representations of preferences assumed under commonly used efficiency criteria, they are empirically based and can be made as precise as desired.

This experimental test was conducted under controlled conditions quite different from an actual decision-making environment. The interval approach to preference measurement also has been used in a more practical setting—a series of extension workshops—as a tool to help farmers think more clearly about their risk preferences. The interval measurements in figure 2 were made at such a workshop. The seventeen farmers for whom absolute risk-aversion intervals were constructed found the choices in the interval measurement questionnaire to be interesting and had little difficulty completing it without supervision. Their preferences ranged from the extremely risk-averse to the extremely risk-loving. Several discernible patterns did emerge, however. Most individuals exhibited increasing absolute risk aversion over lower income levels and decreasing absolute risk aversion at higher income levels. For most, the interval measurement of absolute risk aversion included negative as well as positive values at some income levels. In fact, only four had lower-level absolute risk-aversion functions that were everywhere non-negative. This casts serious doubts on the reliability of single-valued utility functions, which typically restrict the form of the absolute risk-aversion function, and on the applicability of a criterion such as second-degree stochastic dominance, which holds only for decision makers who are risk-averse at all income levels.

Finally, in an application of stochastic dominance with respect to a function concerned with farm enterprise choices under price, yield, and weather uncertainty (King, and Robison, 1981), interval measurements made in the extension workshops were used to order 500 randomly selected farm plans. For the two decision makers whose interval measurements are given in figure 2, each efficient set contained less than ten plans, and only one plan appeared in both sets. This demonstrates that interval measurements can be used to represent differences in preferences and that they can be used effectively to eliminate a large number of choices from consideration in a realistic decision situation.

The Potential Role of Multilevel Programming in Agricultural Economics

Wilfred Candler, Jose Fortuny-Amat, and Bruce McCarl

This paper discusses a new class of problem related to mathematical programming but with two separate decision makers in hierarchical relationship, each with his own objective function and control over distinct but interacting variables. The relationship of this problem to agricultural (energy and environmental) policy problems is developed, together with the relationship of this new problem structure to mathematical programming, game theory, control theory, and principal agent theory. Suggested computational approaches are reviewed, along with the solution to two illustrative examples of the use of the technique.

Key words: agricultural policy, mathematical programming, multilevel programming.

In this paper we wish to take the reader beyond sector modeling to the next logical step, the use of sector models to find optimum agricultural policies. As will be illustrated, this leads to a new model structure, which has been called multilevel programming.

A key characteristic of agricultural (or economic) policy problems is that the government, or other policy makers, have only a limited range of variables under their direct control. Other variables, acreage of crop grown, tons of fertilizers applied, choice of crop, machinery investment, and the like, are decided by a myriad of decentralized decision makers following a variety of behavioral rules. While models have been constructed to reflect the competitive behavior of decentralized decision makers in the agricultural sector, little attention has been given to a clear articulation of policy objectives or the acceptable range for policy variables such as taxes, subsidies, quantitative limitations, or entitlements.

Consider for a moment an agricultural sector model of the CHAC type (Duloy and Norton), in which downward-sloping demand functions and upward-sloping input supply functions are used to calculate equilibrium prices and quantities. Such a model has been used to represent competitive behavior by the agricultural sector. Given such a model, in which the objective function of maximizing the area between the demand and supply functions serves to locate the competitive solution, policy experiments can then be performed to examine the results of price policies, taxes, subsidies, production quotas, supply shortages, and the like. For any one experiment, i.e., for any one setting of the policy variables, the model will yield the corresponding competitive solution. Any number of experiments, limited only by time and the research budget, can be performed. So far so good, but note that this experimental approach finessess the need to state explicitly "the policy problem." Typically, it fails to define clearly (*a*) the full spectrum of variables under the control of the policy maker, (*b*) the acceptable ranges for these variables, or (*c*) the policy objective function.

Authors can be found who will assert that it is better not to be tied to a single objective function, that it is better to present a range of scenarios and let the policy maker choose. Such authors are content to present "good" policy options, without any idea how far short these options fall from the best policy. If we accept the challenge of attempting to find the best policy in the context of a sector model, then it is evident that we have two types of variables (those under the direct control of the policy maker and those not under his direct control) and two objective functions (the pol-

This is Journal Paper No. 8426 of the Purdue University Agricultural Experiment Station.

icy maker's objective function and the objective function that determines the selection of variables not under the direct control of the policy maker). This immediately distinguishes the policy problem from mathematical programming—and from the multilevel (decomposition) algorithms of the type discussed by Dirickx and Jennergren, which are concerned to find efficient solutions to mathematical programming problems with one objective function and one set of control variables—which recognizes only one objective function and only one class of variables (all under the control of a single decision maker). Equally, game theory is of little help because most variables are continuous; and even if we were content with a discrete approximation, this would involve enumeration of the entire policy space and all possible responses to each policy setting. So long would be spent enumerating that we would never have time to choose.

While this paper focuses particularly on the derivation of optimum economic policy, the same model structure can be applied to other policy problems (environment, energy, etc.) or, indeed, to private decision problems with the appropriate hierarchical structure.

In the next section the multilevel programming problem is defined, for the "usual" linear two-level case. The third section relates multilevel to multiobjective programming, and the fourth section shows that multilevel problems can have local optima. A fifth section relates multilevel programming to related problem structures, the sixth section briefly reviews solution principles, and the seventh section presents illustrative numerical results. A final section summarizes the ideas which have been advanced. No automatic, fast, large-scale solution procedures are available, largely because the field is too new for the various suggestions to have been tested and implemented in large codes.

Problem Definition

First consider a standard linear programming problem: P1: Find x_1, such that

$$z_1 = \max_{x_1} c_1 x_1, \tag{1.1}$$

subject to

$$A_{11} x_1 \leq b_1, \tag{1.2}$$

$$x_1 \geq 0, \tag{1.3}$$

where this problem might involve any of the following applications: (*a*) an agricultural sector model (Duloy and Norton) such as CHAC, where the objective function (1.1) serves to locate the competitive equilibrium solution; (*b*) a river basin model (Duloy et al., Kutcher), where (1.1) again serves to find the competitive equilibrium solution; (*c*) and the like.

Now, suppose that a policy maker (*a*) knows the structure and coefficients of P1, and (*b*) can influence through the setting of policy variables some of the parameters within c_1 and b_1 (and even A_{11}, through activities such as research and development and extension), but (*c*) cannot control (any element of) x_1 directly, and (*d*) that the levels of x_1 enter into the utility function $U_2(x_1)$ of the policy maker.

Influencing the size of c_1 typically would be achieved by tax or subsidy policy or possibly by fixing mandatory buying and selling prices. In the case of an input-supplier, c_1 would be influenced directly by the prices he chooses to charge. Influencing the size of b_1 might involve production quotas, set-aside acres or control over quantitative supplies of inputs. Because changes in c_1 and b_1 may have direct costs or benefits to the policy maker, his utility function should perhaps be better expressed as $U_2(x_1, c_1, b_1)$. Note that in these examples we are dealing with strictly hierarchical decision structure. Once the policy maker has decided on the values of c_1 and b_1, the lower level (or behavioral) decision maker simply solves P1, in the light of these values. There is no element of bargaining.

As mentioned earlier, the usual way in which hierarchical decision problems of this sort are studied is to build an explicit model of P1, and then solve it for a range of values of c_1 and b_1, leaving it to the outer decision maker to evaluate his utility function for the resulting x_1, and c_1, b_1.

The traditional approach is basically sloppy since no account is taken of the feasible range for c_1 and b_1, nor is it possible to select the experimental values of c_1 and b_1 in regions of likely interest to policy makers. And finally, it makes very little sense, having gone to the expense of constructing and calibrating P1, to fail to find the optimum available policy. In the next section we touch briefly on the derivation of the policy objective function. In the balance of this section, we simply assume that a satisfactory estimate of the policy maker's objective function U_2 is available and is convex.

Given this assumption, we can state the two-level programming problem as P2: find x_1, x_2, and d_2, such that

$$(2.1)\quad z_2 = \max_{x_2, d_2} c_{21}x_1 + c_{22}x_2 + c_{2d}d_2 + d_2Q_2x_1,$$

subject to

$$(2.2)\quad G_2d_2 + A_{21}x_1 + A_{22}x_2 \leq b_2,$$

$$(2.3)\quad x_2, d_2 \geq 0,$$

where x_1 solves

$$(2.4)\quad z_1 = \max_{x_1 | x_2, d_2} (c_1{}^0 + d_2)x_1,$$

subject to

$$(2.5)\quad A_{11}x_1 \leq b_1{}^0 - A_{12}x_2,$$

$$(2.6)\quad x_1 \geq 0,$$

where x_2 gives the set of allocation policies available to the policy maker, and d_2 gives the set of pricing policies available to the policy maker.

For given $x_2 = \bar{x}_2$, $d_2 = \bar{d}_2$, then (2.4) to (2.6) corresponds to the linear programming problem P1, with

$$c_1 = c_1{}^0 + \bar{d}_2,\ b_1 = b_1{}^0 - A_{12}\bar{x}_2,$$

i.e., it is the inner decision maker's problem, after the policy maker has selected the policies (x_2, d_2) and thereby b_1, c_1.

Restraints (2.2) to (2.3) restrict the acceptable values of the outer (policy) variables d_2, x_2, in the light of the values of x_1.

The outer objective function (2.1) contains linear terms for x_1, x_2, and d_2, and a quadratic term in d_2x_1, because this is the total subsidy or revenue from per unit subsidies and taxes, d_2, multiplied by quantity produced or used, x_1.[1]

In general, the inner problem, P1, could be replaced by any mathematical programming problem; and (2.2) to (2.3) could be replaced by nonlinear constraints, while (2.1) could be of higher order than quadratic.

The important features of the two-level programming problem P2 are (*a*) the hierarchical nature of policy decision making is explicitly recognized, where (*b*) the variables under the control of the policy maker, d_2, x_2, are clearly distinguished from the variables, x_1, which are under the control of the inner (or behavioral) decision maker; and (*c*) the existence of two, potentially conflicting, objective functions is explicitly recognized.

Whether or not an acceptable algorithm for P2 is available, the use of the two-level structure to express a policy problem is a great aid to intellectual rigor. The model structure forces on the policy analyst questions, such as: Which variables are under the control of the policy maker? What are the constraints to acceptable values of these variables? What are the policy objectives? In particular, this formulation should help avoid the misuse of sector models, whereby a simple technical objective is used in place of a behaviorally consistent obejctive. As McCarl and Spreen have said, "A classic example of misuse is one where a research team convinces itself that the country wishes to optimize nutritional production and then the research team replaces (or originally formulates) the objective function to do so. One needs only to wonder how many farmers will forego income to produce calories for the aggregate population to see the fault of this modelling strategy" (p. 98).

Multiobjective and Goal Programming

The typical policy problem is characterized by (*a*) more than one objective or goal that the policy maker wishes to maximize or observe and (*b*) incomplete control over all variables. Multiobjective and goal programming emphasize the former feature, while multilevel programming emphasizes the latter.

A recent review of multiple objective and goal programming makes the distinction between situations in which all variables are, or are not, under the direct control of one decision maker (or committee): "The Goal Programming approach can be an extremely useful tool for situations in which the decision maker . . . commands the system in question (i.e., many private sector decisions) . . ." (Willis and Perlack, p. 71). This is distinguished from policy situations in which no one individual controls all variables. Unfortunately, the literature in this area has failed to recognize that in the usual case, where not all variables are under the control of one decision maker, it can be badly misleading to analyze alternatives as if all variables were under the control of a single decision maker. For most policy (i.e., public sector) problems, this in-

[1] The interaction of d_2 and x_1 may belong in the constraints. However, the problem as stated is analytically simpler and corresponds to Lagrangian relaxation (Geoffrion) of a problem with the quadratic term in the constraints.

validates one-level approaches. Kornai and Liptak recognized that some variables may not be under the direct control of policy makers, but even their contribution assumes harmony in the central and decentralized objective functions.

Equally, the presentation given so far in which a single, known, objective function is assumed to exist for the policy maker might be attacked as too simplistic. Fortunately, the multiobjective and goal-programming literature has considered the problem of how an unknown (or only subjectively known) objective function in several dimensions may be reduced to, or approximated by, a locally linear objective function (Candler and Boehlje, Keeney and Raiffa, Zeleny).

This paper does not pursue the question of derivation of the policy objective in greater depth, because the problem is complex enough even if this objective is known a priori. Let us comment, however, that use of multilevel programming to identify optimum or good policy responses to an arbitrary approximation to the policy objective, in order to improve heuristically the approximation, is completely consistent with the approach being described. If the objective is known, then we can proceed to an optimum or good solution. If the objective is not known a priori, then a detour may be necessary to learn more about the policy objective function before proceeding to results which are more than an aid to heuristic improvement of the statement of the objective function.

Mathematical Difficulty

The multilevel programming problem, unfortunately, is analytically difficult. Multilevel programming problems (which encompass linear programming as a subset) may have many local optima, even though all functions are linear. It is a simple matter to demonstrate this difficulty. As will be shown later, no completely satisfactory algorithm is available for solution of such problems. To see the nature of the nonconvexities which may arise in policy problems, consider the following: P2E, find x_{11}, x_{12}, and x_{21}, such that

$$z_2 = \max_{x_{21}} 2x_{11} + 4x_{12},$$

where $0 \leq x_{21} \leq 1$, subject to

$$\left.\begin{aligned} z_1 = \max_{x_{11},x_{12}|x_{21}} & - x_{11} - x_{12} \\ -x_{11} - x_{21} &\leq -.5 \\ -x_{12} + x_{21} &\leq .5 \\ x_{11}, x_{12} &\geq 0 \end{aligned}\right\},$$

which is the inner problem.

For a given value of x_{21}, the inner problem has solution

$$\left.\begin{aligned} x_{11} &= .5 - x_{21} \\ x_{12} &= 0 \end{aligned}\right\}$$

if $0 \leq x_{21} \leq .5$, or

$$\left.\begin{aligned} x_{11} &= 0 \\ x_{12} &= x_{21} - .5 \end{aligned}\right\}$$

if $.5 \leq x_{21} \leq 1$.

These solution values, together with the resulting objective function value for the outer problem are illustrated in figure 1. Despite the inner problem being a well-behaved linear program for any given value of x_{21}, and despite the outer objective function being linear, there are two local optima, viz., $z_2 = 1$ for $x_{21} = 0$ and $z_2 = 2$ for $x_{21} = 1$.

Quite apart from mathematical difficulties introduced by this feature of multilevel pro-

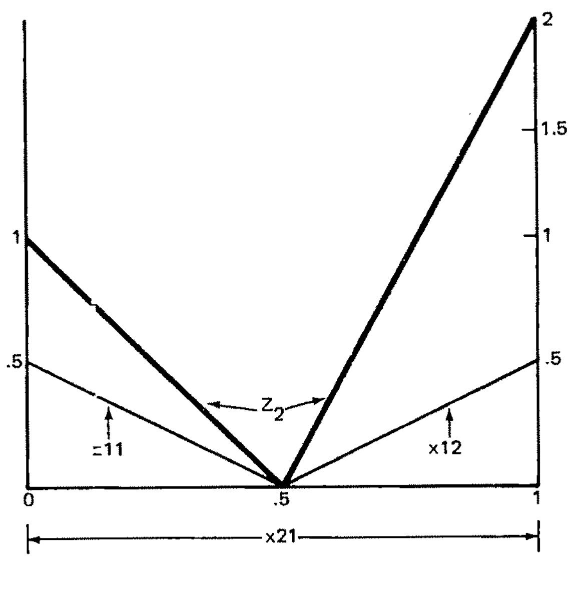

Figure 1. Graphical solution of sample problem

gramming, it also tells us that a mix of good policies may be bad policy. Clearly, a 50:50 mix of the policy of setting $x_{21} = 0$ and $x_{21} = 1$ results in $x_{21} = .5$, with a much lower value of the objective function than characterized either of the policies contributing to the mix.

The existence of more than one local optimum means that the problem cannot be transformed and solved as a linear programming problem. Rather, some form of implicit research of all local optima is called for. As we shall see, various authors have appealed to integer programming, branch and bound, specially ordered sets, and restricted basis entry to achieve their implicit search.

In the special case where the outer decision maker wishes to permit the inner decision makers to maximize their objective function, it may be possible to solve the problem by linear programming (Bisschop et al.). Indeed, in the special case where the inner and outer objective functions are the same and there are no outer constraints, the problem is simply a linear program.

Related Problem Structures

We have now seen that even where all functions are linear, we cannot in general solve even a two-level problem by linear programming. Before passing on to a brief review of computational approaches and empirical examples, it may help put the multilevel problem in perspective if we consider some related problem structures, namely parametric programming, game theory, control theory, and principal agent theory.

Parametric Programming

Looking again at the two-level problem P2 and assuming Q_2 is null so that there are no quadratic terms, it is tempting to guess that the solution to P2 must be among the solutions to the parametric programming problem: P3, for $\phi = 0$ to 1, find x_1, x_2, and d_2, such that

$$(3.1)\quad z_3 = (1 - \phi)(c_{21}x_1 + c_{22}x_2 + c_{2d}d_2) + \phi(c_1^0 + d_2)x_1 \text{ a max,}$$

subject to

$$(2.5)\qquad A_{11}x_1 + A_{22}x_2 \leq b_1^0,$$

$$(2.2)\qquad G_2d_2 + A_{21}x_1 + A_{22}x_2 \leq b_2,$$

$$(2.3, 2.6)\qquad x_1, x_2, d_2 \geq 0.$$

This describes an outer envelope of feasible values of z_1 and z_2, but the solution to P2 may not belong to this envelope. The reason for this is that, for fixed $x_2 = \bar{x}_2$ and $d_2 = \bar{d}_2$, the inner decision maker has the possibility of selecting the x_1 to maximize this objective function (2.4) and without regard to the outer constraints (2.2).

In one example (Candler and Townsley), where (2.1) was maximized over x_2 and x_1 subject to the constraints on P3, the solution value for z_2 was 50,235. When x_2 was fixed at this value and the inner problem resolved, the value of z_2 fell to 15,435, which illustrates the wide degree of discretion that may remain for the inner decision maker even after the values of the policy variables have been fixed.

Game Theory

A bimatrix game may be formulated equivalent to problem P2, with the players being the government and the private sector. The first step in constructing such a game would be to form the payoff matrix, which requires the determination of the strategies available to both players. Let X_2 be the set of admissible strategies for the government. The elements of this set are determined by economic and noneconomic considerations. Assume the government considers only certain discrete levels of policy measures. For example, the government may decide on a tax level among only predetermined figures, say 7%, 8%, or 9%, but it will disregard any other values. Let the set S contain all vectors $(\mathbf{x}_2,\mathbf{d}_2)$ of policy measures that the government considers as practical and feasible candidates to be implemented. The set S evidently is finite. Combining economic and noneconomic reasons results in the following definition for the finite set X_2:

$$X_2 = [(\mathbf{x}_2,\mathbf{d}_2) \geq 0\colon (\mathbf{x}_2,\mathbf{d}_2)\epsilon S,\ A_{11}x_1 + A_{12}x_2 \leq b_1, \text{ and } G_2d_2 + A_{21}x_1 + A_{22}x_2 \leq b_2 \text{ for some } x_1 \geq 0].$$

Let X_1 be the set of admissible strategies for the decentralized decision makers (industry); for any $(\bar{\mathbf{x}}_2,\bar{\mathbf{d}}_2)\epsilon X_2$, this set could be found by enumeration of all extreme points of the subproblem's convex region:

$$A_{11}x_1 \leq b_1 - A_{12}\bar{x}_2$$

$$x_1 \geq 0.$$

Therefore, X_1 is the set of all extreme points of the convex polyhedrons defined by the above set of constraints for all possible values $(\mathbf{x}_2,\mathbf{d}_2)\epsilon X_2$:

$$X_1 = [x_1 \geq 0,\ x_1 \text{ is an extreme point of } A_{11}x_1 \leq b_1 - A_{12}\bar{x}_2 \text{ for some } (\bar{\mathbf{x}}_2,\bar{\mathbf{d}}_2)\epsilon X_2].$$

After defining the sets of strategies for both players, the next step in constructing the bimatrix game is the determination of the payoffs. Evidently, for any triple $(\bar{d}_2,\bar{x}_2,\bar{x}_1)$ such that $(\bar{\mathbf{d}}_2,\bar{\mathbf{x}}_2)\epsilon X_2$ and $\bar{x}_1\epsilon X_1$, the payoff to the government is $c_{21}\bar{x}_1 + c_{22}\bar{x}_2 + c_{2d}\bar{d}_2 + \bar{d}_2 C_2\bar{x}_1$ and the payoff to industry is $(c_1{}^0 + \bar{d}_2)\bar{x}_1$, as given by the respective objective functions. To completely specify the payoff matrix, we will assign the payoff pair $(-\infty,-\infty)$ if for strategy $(\mathbf{x}_2,\mathbf{d}_2)\epsilon X_2$ there is no feasible $x_1\epsilon X_1$.

In order to find a proper solution concept for the game just constructed, some behavioral remarks about its nature should be made. Because the decision-making process is performed sequentially in two stages, with the government announcing its strategy in the first stage, we have a situation where the government acts as the leader and the industry acts as the follower (decides on its plan of action after the government's strategy has been announced). Under these circumstances it has been shown (Simaan and Cruz) that the best strategy to use by the player acting as leader is the Stackelberg strategy.

There are two difficulties with this approach. In the first place, the policy variables d_2,x_2 generally will be continuous variables, whereas the set X_2 would refer to a finite number of discrete values of d_2, x_2. This is not a substantive objection since, in principle, the grid X_2 can be made arbitrarily fine. The substantive objection is that this approach involves an explicit (not implicit) search over the policy grid X_2. For each member of X_2, linear programming problem P1 would need to be solved to find $x_1 = f(\mathbf{x}_2,\mathbf{d}_2)$, and hence $z_2 = g(\mathbf{x}_2,\mathbf{d}_2)$. For any reasonable grid X_2 and nontrivial problem P1, this would be computationally exhorbitant.

Control Theory

Control theory, as reviewed recently by Rausser, presents a somewhat similar problem structure, the major differences being that control theory is concerned with the evolution of a system over several periods in which stochastic elements may be important, learning can take place, and the form of the function determining system evolution is known. By contrast in multilevel programming, we are concerned with a two-stage process operating under certainty, so that stochastic elements and learning cannot occur, and where evaluation of the functional form which determines the evolution of the system is the nub of the problem. Control theory deals with a dynamic system while multilevel programming deals with a static equilibrium. Nevertheless, multilevel programming can be viewed as a special case of control theory.

Principal Agent Theory

A third area of economic inquiry which is related to the problem as formulated above is the area of principal agent theory. This was recently reviewed by Holstrom and deals with the problem of maximizing an abstract functional form subject to a maximum of some problem's objective function. The principal is analogous to the government in our situation and private industry is analogous to the agent. This has been an area of considerable theoretical inquiry; however, it has not, at this point, yielded a rich empirical literature. The distinguishing feature of principal agent theory is that the principal can decide on a level of enforcement effort to influence the behavior of the agent, cf., enforcement effort which might be associated with an effort to fix gasoline prices below their equilibrium value. So again, multilevel programming is a simplification of the general principal agent theory, where enforcement effort is zero.

The formal statement of the principal agent problem can be written (Holstrom, p. 76): P4 find x_1,x_2, such that

(4.1) $\quad \max E\{G[x_2 - s(x_2)]\}$,

subject to

(4.2) $\quad E\{H[s(x_2),x_1]\} \geq \bar{H}$,

(4.3) $\quad x_1\epsilon \operatorname{argmax} E\{H[s(x_2),x'_1]\}$,

(4.4) $\quad x'_1\epsilon X_1$,

where the notation "argmax" denotes the set of arguments that maximize the objective function that follows. In this case, X_2 is the enforcement effort and x_1 the variables not under the direct control of the principal.

Summary

None of the above should be construed to argue that multilevel programming is a more appropriate tool than the other techniques mentioned. Rather, the discussion illustrates the theoretical relationship of multilevel programming to other lines of inquiry. Since multilevel programming is the newcomer in the theories being discussed, we have tried to emphasize that it is genuinely different and to avoid the possibility that it will be dismissed as a special case of already well-understood quantitative techniques.

As illustrated by the recent review by McCarl and Spreen, agricultural economists have been active in the construction of sector models, almost always motivated by an interest in economic development and agricultural policy. An obvious question is: Given a sector model, how can policy recommendations be optimized? It was exactly this question which led to the formulation of multilevel programming by Candler and Norton. It should therefore come as no surprise, that of the alternative analytical techniques, multilevel programming should be the most appropriate for this particular application.

Solution Principles

At this writing, only limited numerical experience exists for the solution of multilevel programming problems. No attempt is made here to provide a comprehensive review of the suggested algorithms; rather, we are concerned to identify the approaches which have been explored and point the interested reader to the relevant papers.

A first "classical" approach, by Fortuny-Amat and McCarl, replaces the inner problem (2.4) to (2.6) by its Kuhn-Tucker conditions, which are then included as explicit constraints in addition to (2.1) and (2.3). As well as the addition of linear constraints, this adds the Kuhn-Tucker complementary slackness conditions. Fortuny-Amat and McCarl replace the complementary slackness conditions by zero-one integer constraints, thus producing a mixed integer programming problem.

Bard and Falk carry out the same transformation but initially ignore the complementary slackness conditions, using the specially ordered sets algorithm (available on Apex 3 software). Bialas, Karwan, and Shaw have shown that a parametric raising of the policy objective, while a complimentary pivot algorithm is used to satisfy the Kuhn-Tucker conditions, can be used to find the global solution to P2.

Bialas and Karwan also have observed that if (2.2) is ignored, then the solution to P2 occurs at an extreme point of the convex hull (2.3), (2.5), and (2.6). They then propose a branch and bound search of these extreme points, starting from the point with highest value of z_2. This corresponds to enumeration of all feasible bases for the inner problem, such that z_2 exceeds the solution value for P2.

Another "classical" approach is due to Bracken and McGill (1973, 1974). It simply recognizes the nonlinear nature of the problem and applies a generalized nonlinear search algorithm: SUMT.

Candler and Townsley assume that $d = 0$, and a myopic search for a better basis is pursued until a local optimum appears to have been reached. At this stage, reduced-cost information is examined to establish a set of vectors, at least one of which must be included in any better basis.

Another special case, where the objective function of the outer problem is in total opposition with that of the inner problem (i.e., a zero-sum situation), has been considered by Falk.

To date, computational experience with all of the proposed approaches has been unpromising. Either the algorithm requires a special purpose code not available in large packages or problem size increases substantially as it is transformed to be solvable by existing large-scale codes.

The largest problem solved to date was for an agricultural region in Mexico. This involved 50 constraints, 300 behavioral variables, and 20 policy variables. A heuristic search procedure was employed, which found a solution value of 49,950 after establishing an upper bound of 50,235. The heuristic procedure is reported by Candler and Townsley. For large-scale problems, this heuristic may still be the most practical approach.

Illustrative Examples

Applications to date have been more illustrative than anything else. Nevertheless, applications have been made in the context of the allocation of irrigation water into a canal

command and optimal pricing policy for a spatial monopolist.

Irrigation Policy

In this case, we considered a model of an irrigation canal command, where policy administrators could control the cotton quota and water releases. Two alternatives were considered for water release, the first where the government controlled only the annual availability of water to the canal command (leaving its distribution by the month to be decided by the farmers, possibly via a cooperative), and the second where the monthly availability of water was controlled by the government. Two policy objective functions were considered. The first involved the maximization of value added at international prices, and the second, the maximization of employment. In all cases, farmers were assumed to maximize value added at local prices (and there are marked differences between domestic and international prices, in this case).

Upper and lower bounds and "high point" solutions for the two policy objective functions are shown in table 1 for both cases, where annual and where monthly water deliveries are controlled by the government.

The upper bounds were obtained by maximizing the relevant objective over all variables (i.e., as if policy and behavioral decision makers were cooperating to maximize the relevant objective). These upper bounds are given in columns 1, 2, and 3. They illustrate that substantial substitution possibilities exist within the model. Thus, depending on choice of objective functions, the value of output at international prices can range from 110,451 down to 39,208; employment can range from 16,894 to 22,435. The extreme difference in domestic and international prices can be seen from the first and third row of table 1.

Lower bounds, columns 4 to 7, are obtained by fixing the relevant policy variables (cotton quota and total water in columns 4 and 5, and cotton quota and monthly water in columns 6 and 7) and maximizing over the behavioral variables (areas of crops) with respect to local prices. In columns 6 and 7, where monthly water allocation is controlled by the government, this change in objective function yields the same plan, i.e., upper and lower bounds coincide, and the given water allocations gives the globally optimum plan with respect to the two objective functions. It should be remarked that the two plans have markedly different implications for employment and value added at international and at domestic prices.

In columns 4 and 5, the lower bound is less than the upper bound, and in each case the value added at local prices has increased (i.e., for these given settings of the cotton quota and total water allocation, farmers have been able to change their cropping pattern so as to increase their incomes, with adverse effects on value at international prices or employment).

It may also be remarked that rounded to the nearest integer (as the results in table 1 have been), column 4 appears to dominate substantially column 5. In fact, the employment lends to five places are

Col. 4	17036.02988,
Col. 5	17036.29331,

so that column 5 does call for more employment than column 4. Given the very high cost of this last fraction of job, in terms of value added (both at local and international prices), it is highly likely that column 4 would be felt to be preferable to column 5.

The lower bounds were obtained by the simple expedient of fixing the policy variables at their upper-bound solution values.

Using a heuristic developed by Candler and Townsley, we were able to search for other, better settings of the policy variables. Only one other good setting, "high point," was found with respect to international prices (yielding 109,183 versus a lower bounds of 107,427 and upper bound of 110,451). Two high points were found with respect to labor. The first (col. 9) was better than the lower bound on employment, but worse than the high point (col. 8) found in an attempt to maximize with respect to international prices. The second high point for labor, while much less than the upper bound, was better than any other known solution where the behavioral decision makers had been free to maximize with respect to their own objective function.

At this stage, no great significance should be attached to the numbers obtained, since this was an "academic exercise" without policy makers' involvement. The important thing is that given a model and given a policy objective function, it is now possible to use the model to search for good settings of the policy variables. Using any of the exhaustive search

Table 1. Policy Alternatives

		Upper Bounds			Lower Bounds				High Points

techniques, one can even derive optimal settings of the policy variables.

Monopolistic Pricing

A second problem (Fortuny-Amat and McCarl) considered involved a fertilizer dealer who enjoyed a geographical monopoly and could take competitors' prices as given. In these circumstances, his control variables were the prices charged for his fertilizers in different forms, always subject to the knowledge that farmers would purchase from the least-cost source. The farmers (behavioral problem) had the choice of purchasing from our fertilizer dealer or from dealers in the neighboring regions, and their decisions with respect to quantities are assumed to be made with cost minimization as the sole objective (we assume farmers need a fixed amount of fertilizer). The dealer of interest wanted to maximize profit which, in this case, involves a decision with respect to price only, since the quantities sold depend on the farmers' decision.

We solved this problem using the Fortuny-Amat and McCarl procedure to obtain the results in table 2.

Note that if the formulation ignored the existence of the sub-problem's objective function, the outer decision maker would act as a monopolist facing a fixed demand and thus could raise prices without limit.

Summary and Conclusions

An uncharitable summary of this paper might be that the authors can recognize multilevel programming problems, but they cannot solve them. Perhaps that is a good summary, but let us state this the other way around:

(*a*) The two-level nature of most policy problems means that they are not generally amenable to solution by mathematical programming. Furthermore, solutions obtained by dint of ignoring the behavioral, or lower level, decision function are likely to be seriously misleading.

(*b*) Multilevel programming provides a useful analytical framework for thinking about policy, because it forces a clear distinction between the variables policy makers' control and those they do not. It provides a quantitive framework for the oft-observed difference between private and public interest.

(*c*) In certain special cases, solutions may be available relatively easily using linear programming, or a suitably modified code (Bisschop et al.).

(*d*) The existing practice of running policy scenarios to scan the policy alternatives can, of course, continue to be used, pending further algorithmic developments. Hopefully, the explicit statement of the two-level problem will, in these cases, be a useful prop to intuition in selecting interesting scenarios to examine.

(*e*) In the meantime, the "unsolved" algorithmic problems of multilevel programming should provide a fertile field for Ph.D. theses, for those suitably qualified and inclined.

Notes

The Impact of Increased Alcohol Production on Agriculture: A Simulation Study

Steven B. Webb

The higher prices of petroleum and risks of an Organization of Petroleum Exporting Countries (OPEC) embargo have stimulated the search for alternative liquid motor fuels, including alcohol from renewable sources (Alcohol Fuels Policy Review, Office of Technology Assessment, Paul). Any plant matter can be converted to alcohol, but in the near future the main input in the United States will be corn, because the technology for using the other inputs is not yet so well developed.

The federal and some state governments have enacted tax exemptions for fuel mixtures that include grain alcohol, i.e., gasohol. Because the alcohol content of gasohol is only 10%, the effective subsidy per gallon of alcohol is ten times the amount of the tax exemption. So, exemption from the 4¢ federal tax gives an effective subsidy of 40¢ per gallon of alcohol, and the effective state subsidies add on another 10¢ to a dollar (in Iowa) per gallon of alcohol (Alston, p. 10). The wholesale price of ethanol is less than a dollar above the pretax wholesale price of gasoline. The enacted subsidies are, therefore, inducing rapid increases in the production and consumption of fuel alcohol. Furthermore, a recent study predicts that after the mid-1980s, fuel alcohol will be increasingly economically attractive even without the subsidy (Schnittker Associates, p. 44).

The supply curve of grain alcohol depends chiefly upon the supply of corn and other feedstocks and upon the supply of capital and labor. In the intermediate and long-run (five years or more), one can assume an infinitely elastic supply of labor and capital to an industry as small as grain alcohol would be even under the most grandiose schemes. Federally subsidized loans for alcohol distilleries will further assure that the supply price of capital does not rise as the industry expands. The slope of the alcohol supply curve will depend chiefly on (in)elasticities of supply and demand in the agricultural sector. Agricultural inputs currently account for over half the cost of grain alcohol.

This paper seeks in one sense to estimate the upward slope of the supply curve of ethanol by estimating the response of agricultural prices to various levels of corn alcohol production. An alcohol fuel program is, on the other hand, an agricultural policy as well as an energy policy. So a second purpose of this paper is to predict the impact of increased alcohol fuel production on important dimensions of U.S. agriculture.

The first section of the paper will describe in detail the linkages between agriculture and alcohol production from corn. The next section tells some relevant features of the model used for the simulation—the U.S. Department of Agriculture's (USDA) NIRAP—and describes the results of the simulation experiments. U.S. agriculture appears well able to adapt to the impact of increased alcohol production. Consequently, the upward slope of the alcohol supply curve will be modest. The third section of the paper describes this supply curve and some other wider implications of the simulations.

The Linkage of Alcohol and Agriculture

The connections between the grain alcohol industry and agriculture may be described in two ways. The demand for agricultural commodities will shift in terms of quantity as a function of the volume of alcohol output. Likewise, the cost of producing alcohol will depend on the price of agricultural commodities.

Physical Flows

Producing a gallon of alcohol requires 0.4 bushels of corn. So, we shall model the input for a fuel alcohol program as an outward shift in the demand curve for corn, a shift whose size is directly proportional to the size of the program. Distillation from corn yields marketable by-products, whose value reduces the cost of alcohol production by about one-fourth (Alston, p. 6; Office of Technology Assessment, pp. 11–12; Meekhof, Gill, Tyner, p. 15). Conventionally this by-product is a mash, which when dried is marketed as distillers dry grain (DDG). Production of a gallon of alcohol yields 6.8 pounds of DDG; as cattle fodder it will substitute for about 3.4 pounds of soybean meal. In order to save the cost of drying the mash into DDG, many

Steven B. Webb is an assistant professor, Department of Economics, University of Michigan.

The author wishes to thank Terry Alston, Joe Asbury, Leroy Quance, Wally Tyner, two referees, and especially Dave Watt for their many valuable suggestions. Any errors that remain are, of course, the responsibility of the author.

plans call for using the mash wet in feedlots adjacent to distilleries. In either case, though, we can assume the same ratio of substitution between soybean meal and by-products per gallon of alcohol obtained by conventional dry milling. It is also possible to produce ethanol from corn by a wet milling process that yields corn oil and gluten meal as by-products (Alston, p.5). As DDG displaces some soybean meal in the fodder market, it will become desirable to have corn oil replace corresponding amounts of soybean oil. Therefore, a mix of the dry milling and wet milling processes probably will emerge. Because dry milling produces more alcohol per bushel of corn, and because soybeans are about four-fifths meal, dry milling will be the basis for the simulation here. The price of soybean meal per weight is just over four-fifths the price of soybeans. So a pound of DDG is equivalent to about two-fifths of a pound of soybeans, and each gallon of alcohol will yield by-products equivalent to about .045 bushels of soybeans.[1] We can, in short, model the impact of each billion gallons of alcohol production by shifting out the corn demand curve by 400 million bushels and shifting in the soybean demand curve by 45 million bushels.

Price Linkage

Both the input and output flows between alcohol distillation and agriculture contribute to the upward slope of the alcohol supply curve. Obviously, as increased alcohol production shifts out the demand curve for corn, the resulting higher price of corn will raise the cost of alcohol production. Increased alcohol production also would increase the supply and thus drive down the price of the by-products—DDG—and of the soybeans for which they substitute. Lower prices for by-products raise the total cost of the alcohol. With corn selling at \$3.70 per bushel in December 1980 and DDG at \$120 per ton (half the price of soybean meal) and with 20% inflation of Alston's estimate of other costs (\$.55/gal. in 1978 dollars, p. 6), ethanol would cost \$1.67 a gallon. Each percentage point rise in the price of corn would raise the cost of ethanol 0.85%, and each percentage point fall in the price of DDG would raise ethanol cost 0.25%.

Simulation with NIRAP

The National Interregional Agricultural Projection (NIRAP) system is a computerized simulation model of the U.S. agricultural sector. A model of this complexity is necessary because of the numerous interactions that would take place as alcohol production simultaneously increased the demand for corn and the supply of a soybean substitute (DDG). Marginal land would be drawn into corn cultivation. There would be substitutions in production as land was switched to corn from other crops, especially soybeans. There would be substitution in fodder usage, soybeans for corn. There would be substitution in animal raising and in meat consumption as animals needing relatively more soybeans (cattle) were substituted for those needing mostly corn (hogs and chickens). Exports would react to any changes in domestic prices. NIRAP incorporates these interactions into its simulations.

Simulations

For the principal set of simulations, alcohol fuel output was 10 billion gallons annually. This is an upper bound on eventual production levels, since it would almost suffice for gasohol completely to replace straight gasoline at current levels of use. Ten billion gallons of alcohol per year would require corn inputs equal to about half of current U.S. production. The structure of the NIRAP model is such that the effects of alcohol production are not exactly proportional to the volume of alcohol produced. So some results from simulations of 5 billion gallons of alcohol per year are reported to give the reader a sense of the nonlinearities.

Shifts in the export demand curves simulated the impact of a fuel alcohol program. The export demand curve for corn was shifted up by an amount corresponding to the input requirements for fuel alcohol production, and the export demand curve for soybeans was shifted down by an amount corresponding to the by-product output of 1979 and 1985. A longer phase-in period, 1979 to 1990, yielded similar results.

Measures of Impact

To measure the impact of grain ethanol production, the outcomes in various scenarios are compared with a base case in which there is no alcohol production and also no explicit government price support programs. The NIRAP projections include a rate of inflation, which is certainly realistic in general but is not likely to be precisely accurate in predicting price levels ten or twenty years hence. So, the differences between values in the base case and those in the simulated scenarios are reported as percentage changes from the base case value. Table 1 reports for several simulations the percentage changes in some of the key variables in agriculture.

For the purpose of estimating the slope of the ethanol supply curve, the changes in the price of corn and soybeans are most relevant.

For the purpose of understanding how the structure of agricultural production and consumption will change in response to large-scale ethanol production, we also want to look at changes in other key prices—wheat, beef, and pork. Even more revealing will be the changes in the production quantities of corn, soybeans, wheat, and meat, and in the amounts of these commodities that are exported.

[1] One gallon of ethanol yields 6.8 lb.DDG = 3.4 lb. soybean meal = 2.7 lb. soybeans = .045 bushels of soybeans.

Table 1. Projected Effects of Grain Alcohol Production on Selected Variables in the Agricultural Sector

Column		2	3	4	5	6	7
Alcohol output (billion gal./yr.)	5	10	10	10	10	10	10

output	−2.3	−3.[illegible]	−4.0	−4.0	−3.7	−4.5	−4.6
Farm prices (aggreg. index)	3.6	11.[illegible]	8.3	5.9	14.1	10.5	7.4
Net farm income	7.7	32.[illegible]	18.3	11.4	41.2	23.6	14.3

[a] Compared to the base case projection with no alcohol production and no price supports. The percentage change was calculated as the difference from the base case divided by the value in the base case.

The ramifications of a fuel alcohol program for Americans' overall lifestyle show up in two variables. The changes in real net farm income show the benefits that will accrue to farmers. The changes in an index of average agricultural prices (paid to farmers) reveal the adverse impact on all consumers' budgets.

Results

The first 4 columns of table 1 show the projected values of key variables in simulations using the standard assumptions about input and output flows. Each billion gallons of alcohol requires 400 million bushels of corn and yields by-products that substitute for 45 million bushels of soybeans. The maximum levels of alcohol production—5 billion gallons annually for column 1 and 10 billion gallons for columns 2-4—are reached by 1985 and maintained thereafter.

Price Effects

Corn's price reacts most dramatically to alcohol production. Each additional billion gallons of alcohol per year raises the price of corn by about 4%. The relationship between alcohol production and corn price is linear in logarithms; each additional billion gallons of alcohol raises the natural logarithm of the corn price by the same amount. 0.038 in 1990. Alcohol production drives down soybean prices, as one would expect, because of the by-product DDG substituting for soybean meal. The relation for soybeans is complicated, however, by the substitution with corn in both production and consumption, induced by the strong rise in the price of corn. Still we can say that each additional billion gallons of alcohol production per year will lower the price of soybeans and their substitutes (DDG) on the order of 1%. This is not out of line with the findings of Meekhof, Tyner, and Holland, using a model with only corn and soybeans, that increasing ethanol production from 1 to 2 billion gallons would raise the price of corn 5.5% in the early 1980s and lower the price of soybeans 2%.

Alcohol production also affects prices of commodities not directly involved. Wheat prices would rise, but only about half a percent for every billion gallons of alcohol annually. Pork prices reflect the effects of higher feeding costs, with the percentage rise in projected pork prices being almost half as large as the percentage rise in corn prices. Beef prices react to at least three influences: high pork prices shift consumer demand toward beef; high corn prices raise the production cost of beef; and falling soybean prices lower costs. Because the last effect goes in the opposite direction from the first two and because the effects are nonlinear, beef prices fall for low levels of alcohol production and rise for high levels. The overall index of prices paid to farmers goes up a percentage point or less per

billion gallons of alcohol output. Although the effect on the overall consumer price index would be imperceptible, the rise in meat prices would be noticed and might arouse political opposition to gasohol subsidies.

Output Effects

Increased alcohol production would push up corn output almost as much as corn prices. The percentage of decline in soybean production is, on the other hand, around twice the percentage of decline in price. This happens because the increased availability of DDG shifts the soybean demand curve leftward, while the switching of land from soybeans to corn shifts the soybean supply curve also to the left. Wheat output increases in order to fill the increased need for corn substitutes. One can visualize the wheat-growing regions expanding slightly, perhaps at the expense of the corn-soybean regions, while the crop mix in corn-soybean regions shifts strongly toward corn.[2] The small change in projected beef production reflects that the price rise resulted from nearly equal upward shifts in its supply and demand curves. The decline in pork output, much smaller than the rise in price, confirms that the supply curve shifted up along a relatively static demand curve.

Exports

The major changes in exports, caused by alcohol production, are the decline of corn exports and rise of soybean exports. Wheat exports actually rise some, presumably to fill the gap in world markets left by the decline of corn exports. The net change in the trade balance would be positive, chiefly because of the higher corn prices.

Without By-Product Sales

One of the major uncertainties about large-scale grain ethanol production is how the corresponding large output of by-products will be marketable. In other words, will one billion bushels of DDG substitute for soybeans at the same ratio that 10 million bushels do at present? The scenarios discussed so far presume that they will. Realistically, one must expect some decline in the price of DDG and other alcohol by-products relative to the price of soybean products.

To see an extreme upper bound on the effect of diminishing opportunities for utilizing alcohol by-products, columns 5,6, and 7 of table 1 report results of a simulation where it was assumed that no alcohol by-products entered the agricultural economy. Except on soybeans, the effects in this no-by-product scenario, which has the same alcohol output as columns 2,3, and 4, do not differ much from the standard scenario. The prices of corn, wheat, beef, and pork rise a little more in the no-by-product scenario, and their outputs rise slightly less or, in the case of pork, fall slightly more. Net farm income rises about 30% more in the no-by-product scenario. The big change, of course, is for soybeans, whose price and output rise rather than fall.

Any other reasonable scenario for the prices and uses of by-products would yield results intermediate between those in columns 2–4 and those in columns 5–7.

Further Implications

The previous section reports the simulated effects of increased alcohol production on the prices and flows of commodities in the agricultural sector. These changes will have some broader ramifications for the supply price of ethanol, for the income of farm households, for the efficiency losses that our society would incur by subsidizing fuel alcohol, and for the moral issue of producing fuel from grain while millions of people in the world go hungry.

Ethanol Supply Curve

The long-run ethanol supply curve starts at a height approximately equal to its current cost, $1.67 per gallon, and slopes upward in accordance with the impact of ethanol production on agricultural prices. As described earlier, the cost of ethanol production rises 0.85% for each percentage point rise in the price of corn and 0.25% for each percentage point fall in the price of DDG. Each billion gallons of ethanol production will raise the price of corn 4% and lower the price of soybeans (DDG substitute) about 1%. The ethanol supply curve will, therefore, rise 3.65% for every billion gallons of ethanol. So producing 10 billion gallons of ethanol annually, the upper bound, would push its price up 36.5%, to around $2.30 per gallon in 1980 dollars.

Farm Incomes

How the gasohol program "plays in Peoria" and elsewhere in the rural Midwest depends chiefly on what it does to farm incomes—measured by "real net farm income" in the NIRAP model. Gasohol will be a political success with farm constituencies. In 1990, every additional billion gallons of alcohol annually would raise real net farm incomes by over 1.5%. The boost to net farm incomes from a given level of alcohol production appears to diminish over time. This occurs because land costs, which are netted out in the calculation of net farm income, rise in response to the greater demand for agricultural output. So if we count land rents as part of the profits of agriculture, rather than as part of the cost, then the supplement to farm income appears more accurately in the calculation for 1985: each billion

[2] The version of the NIRAP model that I used does not explicitly calculate the amount of land in cultivation.

gallons of annual alcohol production raises farm income by 2% to 3%.

As a policy to augment agricultural income, ethanol production subsidies should be compared with existing price support programs. To compare current crop diversion schemes with ethanol production, the NIRAP program was run with the constraint that government payments to farmers be sufficient to give the same net farm income as in the simulation for 10 billion gallons of ethanol production. The simulated necessary government outlays were 4.4% of potentially marketable output in 1985 6% in 1990, and 1.9% in 2000. Government payments were, in comparison, below 1% in the mid-1970s but over 6% in the late 1960s (USDA 1977, p 32).

Social Costs

Standard supply and demand analysis reveals the social cost of a fuel alcohol subsidy compared to a free market situation. The area under the fuel alcohol demand curve is the benefit to society from alcohol production—a gain divided between increased surplus for liquid fuel consumers and decreased resource costs of producing nonalcohol fuels. The area under the alcohol fuel supply curve is the resource cost of its production. So the social loss from a fuel alcohol subsidy is the area that is between the two curves, to the right of the equilibrium without a subsidy, and to the left of the equilibrium with a subsidy. When, as now, there would be virtually no fuel alcohol production without a subsidy, then the area of social loss is most of the value of the (implicit) government subsidy. The Schnittker Associates predict, however, that by 1985/86 the price of oil will have risen enough relative to the price of corn so that substantial amounts of fuel alcohol would be produced even without a subsidy (p. 44). In that event the social loss from the subsidy, if it remains, probably would be well under half the total value of the subsidy. In either case, the more responsive the agricultural sector, i.e., the more readily it diverts resources away from alternative uses and therefore the flatter the alcohol supply curve, the greater is the social cost arising from a given per gallon subsidy, and the smaller is the proportion of the subsidy that would be a pure transfer to the farmers' net income.[3] Clearly then, the implication of the NIRAP simulation, that the alcohol supply curve is relatively flat, means that the gasohol subsidy will be effective as an energy policy to reduce dependence on petroleum but will be a socially wasteful way to subsidize farm incomes

[3] See Webb (1981) for a fuller discussion. To the extent that present programs subsidize farm incomes by diverting some resources, e.g., land, from their highest valued uses, the social cost of replacing these programs with the fuel alcohol subsidy would be less than when compared with the free market situation.

Food versus Fuel

The moral question about producing fuel from resources that could feed hungry people is addressed most directly by looking at the changes in exports, especially of wheat. The main U.S. export that feeds the world's poor is wheat. Developing countries buy two-thirds of U.S. wheat exports and use them mostly for human consumption (USDA 1979, pp. 49–50). In the NIRAP simulations, fuel alcohol production actually caused wheat exports to increase Granted, the increased exports probably take the place of corn as fodder, but the wheat price rise is only 2% to 6% and so would do little to discourage human consumption.

Conclusions

The U S. agricultural economy as modeled in the NIRAP program appears to be capable of adjusting without major difficulties to even high levels of fuel alcohol production. The price of corn and cost of alcohol would rise significantly but not so high as to rule out the possibility of replacing with alcohol a tenth of current gasoline consumption. This prediction of great responsiveness by American agriculture is not surprising in view of its historical ability to adjust to shocks at least as large as those resulting from high levels of alcohol production. The extensiveness of the relationships modeled in NIRAP not only gives insights into the indirect effects of increased alcohol production but also probably accounts for why the direct effects are so mitigated.

Impact of the Farmer-Owned Reserve on Privately Owned Wheat Stocks

Jerry A. Sharples and Forrest D. Holland

Peck and Gray, in a recent article, point out that private stockholding tends to be neglected in the literature on grain reserves. They emphasize that the relationship between publicly controlled reserves and privately owned stocks is crucial in determining the effectiveness of a grain reserve program. We agree. In this paper we further probe the private demand for wheat stocks. Now that three years' data are available on the U.S. farmer-owned reserve (FOR) it is possible to make an initial estimate of the impact of subsidized wheat reserves on privately owned wheat stocks.

Wheat started entering the FOR during the 1977/78 marketing year. The quantity in the reserve increased until January 1979, when 413 million bushels were accumulated. In May 1979, the wheat price reached the release level and farmers started withdrawing wheat from the reserve. One would expect that the reserve represented an additional demand for wheat during that time of accumulation raising the wheat price. But the price impact would depend upon the extent to which the wheat put into the reserve otherwise would not have been stored by farmers. We hypothesize that wheat stocks accumulated in the FOR partially substitute for wheat that otherwise would have been stored by farmers. If there is substitution, the effectiveness of the reserve as a price-moderating policy tool is reduced.

We have two purposes. First, to estimate the impact of the FOR on the demand for year-ending wheat stocks and second, to demonstrate the potential of a little-used functional form for estimating the demand for stocks.

The Model

The supply-of-storage theory is used in this paper to explain stockholders' behavior. From that theory we derive a demand-for-stocks function that relates current season wheat price with the quantity of carryover wheat stocks. The supply-of-storage theory has been discussed by Working and Labys and recently applied by Peck to the wheat market. The supply-of-storage theory postulates a positive relationship between the "price of storage" (a discounted, expected future price minus the current price) and the quantity stored. In this analysis the quantity of wheat, S, remaining in storage at the end of the marketing year is a function of expected return, $E(R)$, i.e.,

$$S = f[E(R)], \quad \text{where} \tag{1}$$

$$E(R)_t = P^*_{t+1} - P_t - C_t, \tag{2}$$

and P^*_{t+1} is expected wheat price the next year, P_t is wheat price in the current year, and C_t is the variable cost, including an interest charge, of storing one unit of wheat. For simplicity, it is assumed that there is no limit to storage space for wheat in the United States.

We postulate the relationship between stocks and expected return to be as shown in figure 1.[1] This relationship illustrates two purposes for holding stocks: for convenience (often called pipeline or working stocks) and for speculation. Pipeline stocks are held by processors and traders to enable them to utilize their plant and equipment and to facilitate trade. These stocks are normally hedged on the futures market, and the quantity held is not very responsive to changes in expected return from storage. Pipeline stocks are held even when expected return is negative. Most of the stocks shown in figure 1 with negative expected returns would be pipeline stocks.

Speculative stocks are held with the expectation of a positive return from storing wheat. Consequently, speculative stocks are very responsive to the level of expected return to storage. Most speculative stocks appear to be unhedged stocks owned by wheat producers.[2] For a large number of speculators with identical expected returns, the curve in figure 1 would be perfectly elastic at $E(R) = 0$. But in this case $E(R)$ represents an aggregate estimate of differing expected returns of

The authors are agricultural economists, International Economics Division, Economics and Statistics Service, U.S. Department of Agriculture, and are located in the Department of Agricultural Economics, Purdue University.

Helpful comments were provided on earlier drafts by David Bessler, James Binkley, Harlan Burnstein, Bob Jones, Marshall Martin, Ronald Meekhof, Anne Peck, John Spriggs, Dick Todd, Carl Zulauf, and an anonymous reviewer.

[1] Strictly speaking, figure 1 does not show a supply-of-storage function since $E(R)$ contains both the price of storage and storage costs. However, figure 1 is useful for this analysis.

[2] A USDA survey showed that on 1 Jan. 1979, 50% of U.S. wheat stocks were stored off the farm but 62% of these off-farm stocks were owned by farmers. If it is assumed that all on-farm stocks are farmer-owned, then on 1 Jan. 1979, farmers owned 81% of U.S. wheat stocks. The same survey the two previous years showed similar results (reported in USDA, GrII-1 25 Jan. 1977 and 1 Feb. 1979).

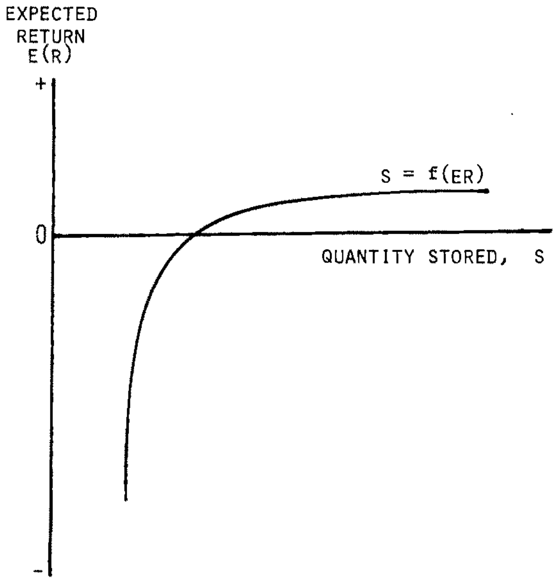

Figure 1. Hypothetical year-end stocks function

many speculators. Each speculator may have different values of P^*_{t+1}, C_t, and P_t. Thus, there is a positive slope to the curve for values of $E(R)$ near zero.

Substituting (2) into (1) gives

$$S_t = f(P^*_{t+1} - P_t - C_t). \tag{3}$$

This stocks function can be transformed into a stocks demand function (where S_t is a function of P_t) if values of expected price, P^*_{t+1}, and holding costs, C_t, are held constant. The relationship between S_t and P_t is expected to be negative. Given a price expectation for next year and a constant holding cost, as current price increases, expected returns from storing wheat decreases and thus the quantity stored decreases.

The relationship between the quantity of wheat stocks in the farmer-owned reserve and the wheat market price is difficult to handle in theory. This demand relationship is believed to be both discontinuous and nonsymmetrical. Two examples of modeling the demand for FOR stocks are presented in Bredahl, Meyers, and Womack and in Sharples. The purpose of this paper, however, is not to estimate participation in the FOR, but rather to estimate the impact of the FOR on the total quantity of stocks. Thus, FOR stocks are assumed exogenous in this analysis.

The FOR is a complicated program with many administrative provisions. For an explanation of the FOR, see Burnstein. The essence of the program, however, is to subsidize private stockholding when the wheat market price is below a specified release price. Thus, the FOR would be expected to increase private stocks, *ceteris paribus*. In this study the relationship between the FOR and the total stocks function is assumed to be simple:

$$S_t = f(P^*_{t+1} - P_t - C_t) + \gamma(FOR), \tag{4}$$

where S_t is privately owned year-end wheat stocks (including FOR stocks), and *FOR* is quantity of wheat stocks in the farmer-owned reserve. The value of γ is expected to be $0 < \gamma < 1$, i.e., a bushel added to the FOR increases total privately owned stocks by less than one bushel. If γ is near 1, the FOR program is effective in increasing total stocks. If γ is near zero, the FOR program is ineffective. The value of γ likely is not a constant; it probably is positively related with the size of the FOR and with price. But because there are only two positive observations for FOR in our data set, γ is assumed constant.

Estimation

In this section an estimate of equation (4) is obtained using annual data from 1972/73 to 1978/79. Wheat stock demand curves are derived from the estimated equation for ending stocks in 1977/78 and 1978/79. The impact of the FOR on the stock demand curves those years also is estimated.

Storage costs, C_t, in equation (4) are

$$C_t = I_tP_t + V_t, \tag{5}$$

where I_t is the interest rate, and V_t is the variable cost of storing a bushel of wheat.

A simple expectations model is used as a proxy for the aggregate of all wheat speculators' price expectations:

$$P^*_{t+1} = (P_t + P_{t-1} + P_{t-2}) \div 3. \tag{6}$$

This naive formulation assumes that speculators expect the price next year to be a simple average of the wheat price over the three most recent years.[3]

In order to incorporate several desirable properties, discussed below, the following functional form is used to represent the relationship between privately owned wheat stocks and expected return from storage:

$$S_t = \alpha[K - E(R)_t]^\beta + \gamma(FOR_t), \tag{7}$$

where K is an assigned constant, discussed below. The signs of α and β are expected to be positive and negative, respectively. Note in equation (7) that when the expected return approaches K, the value of S approaches infinity, and when $E(R)$ approaches negative infinity, S approaches zero. With the appropriate selection of K, equation (7) will approximate the form shown in figure 1. In order to prevent negative numbers from being raised to a

[3] More complex expectation models could have been used. The results indicate, however, that this naive model performs quite well. We also tried adjusting the prices in equation (6) for inflation. This expectation model gave a better estimate for 1979/80 stocks but over the fit period, it had a lower R^2.

negative power in equation (7) the value of K must be larger than the largest observed value of $E(R)$, i.e., .29 in 1976/77 (see table 1). Also, the level of K has an impact on the price elasticity of the stocks demand functions derived from equation (7). Relatively small values of K force the demand functions to be less elastic at high prices than at low prices—a condition expected by Hillman, Johnson, and Gray. Alternative values of K were tested and R^2 was maximized when $K = 0.6$, a value that met both of the above criteria.

Equation (7), with $K = 0.6$, is estimated using data for the seven marketing years 1972/73 to 1978/79 (table 1). 1972/73 appears to have been the beginning of a structurally changed wheat market. Exports dramatically increased that year to a higher sustained level. By the end of the year most CCC-owned wheat stocks were sold. Modeling this seven-year period is simplified because (*a*) the market price is always above the loan rate, so the influence of the price support feature of the wheat program is minimal; and (*b*) the inventory of CCC-owned wheat stocks is insignificant, thus their impact on private stockholding may be ignored.

The estimated stock supply function is[4]

$$(8)\quad S_t = 609(0.6 - E(R)_t)^{-.512} + .86(FOR_t),$$

where the adjusted $R^2 = .99$. The estimated stock function, assuming no farmer-owned reserve, is shown in figure 2. As can be seen by the R^2 value and the plots in figure 2, the equation fits the data well. The largest difference between the estimated and actual values is for 1973/74, where the equation overestimates the actual value by 29 million bushels (9%). Including the impact of the FOR stocks the last two years, the equation overestimates ending 1977/78 stocks by 3% and underestimates the 1978/79 stocks by 3%.

Equation (8) may be expanded to

$$(9)\quad S_t = 609\left[0.60 - \left(\frac{P_t + P_{t-1} + P_{t-2}}{3} - P_t - IP_t - V_t\right)\right]^{-.512} + .86(FOR_t).$$

Derived stocks demand functions are obtained for 1977/78 and 1978/79 by substituting values for lagged prices, interest, and variable storage costs into equation (9). These values are obtained from table 1. The resulting demand equations are

$$(10)\quad S_{77/78} = 609(.764P_{77/78} - 1.24)^{-.512} + .86(FOR_{77/78}),$$

$$(11)\quad S_{78/79} = 609(.755P_{78/79} - 0.82)^{-.512} + .86(FOR_{78/79}).$$

[4] The Time-Series Processor package was used on the CDC 6500. Standard errors for the estimated parameters were not obtained using the iterative least-squares technique.

Equations (10) and (11) are shown in figure 3 with the impact of the FOR omitted. These curves are estimates of what the stocks demand curves would have been without the FOR.

Assuming no FOR stocks, the stocks demand curve for 1978/79 lies to the left of the 1977/78 curve, and is less elastic (elasticities are given in table 2). This is so for two reasons. First, according to the simple price-expectations formula, speculators have lower expectations of future prices in 1978/79 than in 1977/78, for a given current price. For example, if the market price is \$3.00 in 1977/78, the price expected for 1978/79 by speculators in 1977/78 is $(3.00 + P_{t-1} + P_{t-2}) \div 3 = (3.00 + 2.73 + 3.56) \div 3 = \$3.10$. If the market price is \$3.00 in 1978/79, then speculators expect the price the following year to be $(3.00 + 2.33 + 2.73) \div 3 = \$2.69$. Second, costs of holding stocks are higher in 1978/79 than in 1977/78 because both the interest rate and variable storage costs increase (table 1).

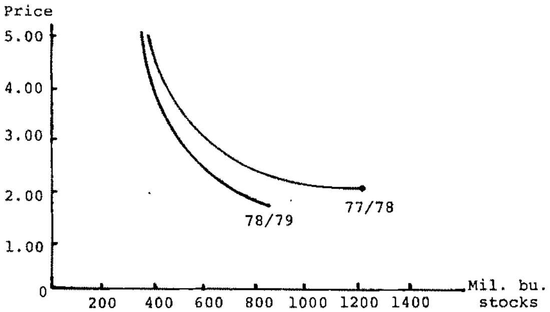

Figure 3. Demand for privately-held, year-end wheat stocks, 1977/78 and 1978/79, omitting impact of the FOR

The estimated value of γ in equation (7) indicates that privately owned wheat stocks increase .86 bushels for each bushel put into the FOR. This suggests that the FOR is effective in accomplishing one of its objectives—to increase stocks when the market price is below the release price.

The impact of the FOR on the wheat market may be illustrated for the 1977/78 marketing year assuming $\gamma = 0.86$. Without the FOR that year, the demand-for-private-stocks function would have shifted left by $(340 \times 0.86) = 292$ million bushels. This reduction in demand would have dropped the season average wheat price to the price support of \$2.25 per bushel.[5] If not supported, the price would have been lower. With the wheat price at \$2.25 rather than at \$2.33 in 1977/78, domestic use would have increased about 6 million bushels, exports would have increased 26 million bushels, and the net change in total stocks would have been an offsetting decrease of 32 million bushels. The price

[5] Price elasticity of demand is assumed to be −0.2 for domestic use and −.6 for exports. Elasticity of demand for stocks is obtained from the estimated equation (see table 2).

Table 2. Elasticity of Demand for Wheat Stocks at Selected Prices for Demand equations (10) and (11); *FOR* = 0

Price	Equation (10) 1977/78	Equation (11) 1978/79
5.00	−0.77	−0.65
4.00	−0.88	−0.70
3.00	−1.15	−0.80
2.00	−3.03	−1.12

Note: For the demand function of the form $S = L_0 + \alpha(L_1P - L_2)^{\beta}$, the price elasticity of demand is $\epsilon = \beta\alpha(L_1P - L_2)^{\beta-1}(L_1)(S^{-1})(P)$.

support program, in effect, makes the demand for stocks perfectly elastic at the wheat loan rate. It would have offset partially the stocks-reducing impact of not having the FOR in 1977/78.

The estimate of the impact of the FOR on private stocks is admittedly crude. Only two years' observations on the FOR are included in the data set. The estimate of γ captures the net effect of all exogenous shifters of the stock demand function those two years—not just the impact of the FOR. There are two reasons to believe that the value of γ overestimates the impact of the FOR. First, the wheat-marketing system had unusual difficulties in 1978/79 getting grain to terminal markets from early spring until after the end of the marketing year on 31 May. The Great Lakes opened late. Later, a major railroad serving wheat states was shut down These factors likely restricted marketings and increased ending stocks while only having a smal impact on season-average price. Second, the quantity of pipeline stocks may be positively related to the volume of wheat marketed. The average volume of wheat marketed during the two sample years containing the FOR exceeds the average of the sample years by 264 million bushels. The estimate of γ would capture this impact as well as the impact of the FOR. It is hypothesized that the two items listed above shifted the stocks demand function right during the sample years containing the FOR. If the hypothesis is true, the contribution to wheat stocks provided by the FOR is overestimated.

Equation (9) was used to estimate private stocks at the end of the 1979/80 marketing year using the data in table 1. The estimated value of 634 million bushels underestimates the preliminary actual value of 712 million bushels by 11%. The shock to the wheat market of the U.S.-Soviet trade suspension in January 1980 may have been a factor contributing to the underestimate.

Implications

The sample size and the degrees of freedom in this analysis are small, so the results must be viewed with some skepticism. Also the quantity of stocks held surely is determined simultaneously with other uses, price, and government action. The evidence, however, indicates that the FOR provided a substantial additional demand for wheat in 1977/78 and 1978/79—years when the FOR was being filled. The estimated value of γ in equation (7) is 0.86: one bushel of wheat placed in the FOR increases the total quantity of stocks demand by 0.86 bushels.

The supply-of-storage concepts used here appear to explain the wheat stockholding actions of private firms in recent years. Also, the functional form used for estimation has several useful attributes. First, it relates well to the hypothesized relation between stock size and expected net return to storage as drawn in figure 1. Second, the price elasticity along the demand curve changes as price changes. Specifically, it is possible for the elasticity to decrease as price increases—an attribute not associated with conventional demand equations. Third, it allows the demand curve to shift over time in response to changed price expectations as well as changed storage costs and interest rates.

As more data and experience with the FOR are obtained, a more thorough examination of the hypothesized relationship between the FOR and the demand for grain stocks may be done. One possibility for overcoming the small number of observations would be to use state data. With an expanded sample, several additional questions could be examined. Is γ in equation (7) positively correlated with price and the size of the FOR? What is the nature of the demand for stocks when price is above the FOR release level? What is the appropriate level of K in equation (7)? A test of the latter question would test the assertion by Hillman, Johnson, and Gray that the price elasticity of demand for privately owned stocks is less elastic at higher prices. This is a key issue when analyzing stability and grain reserves.

Food Demand and Savings in a Complete, Extended, Linear Expenditure System

David B. Eastwood and John A. Craven

Demand equations derived from the classical, constrained, utility-maximization problem state that quantities demanded are functions of all prices and income. An implication is that consumer purchase decisions are interrelated and should be viewed from a systems context. Recent economic events have focused attention on the high prices of energy, medical services, food, and housing, as well as the low level of consumer savings. Such concerns make it desirable that we have estimates of a set of parameters which will allow inferences to be made about the probable response of food demand and savings to changes in consumer income and a comprehensive set of consumer prices.

The purpose of this note is to present and compare the parameter estimates and systems projections obtained from two alternative formulations of Lluch's extended linear expenditure system (ELES). Savings is explicitly introduced into both variants by the constrained maximization procedure. From a practical viewpoint, we delineate a set of demand categories which we feel are more relevant to the study of current economic problems than those used in most published studies.

The Model

Lluch develops the ELES via the constrained maximization of an intertemporal Klein-Rubin utility function subject to a budget constraint in which personal income is the limiting exogenous variable.[1] Howe, by making a simple assumption about the savings behavior of consumers, has shown that the ELES also can be obtained through the constrained maximization of a static Klein-Rubin utility function.[2] Howe's approach is outlined below.

Assume in each time period that (a) a consumer's preference ordering can be represented by the Klein-Rubin utility function, and that (b) he allocates income among n consumption categories and an $(n+1)$th category that is savings. Stated in mathematical terms, the consumer's maximization problem is as follows:

$$\text{(1)} \qquad \text{maximize } U = \sum_{i=1}^{n+1} \beta_i \log (x_i - \gamma_i),$$

$$\text{(2)} \qquad \text{subject to } \sum_{i=1}^{n+1} p_i x_i = y,$$

where U is utility, the x's are quantities, the p's are prices, y is income, the β_i and γ_i are parameters, and the subscript refers to a specific commodity. By assuming that the γ for savings, S, is zero, Howe obtains the demand and savings equations of the system which are identical to those of Lluch:

$$\text{(3a)} \qquad x_i = \gamma_i + (\beta_i/p_i)(y - \sum_{j=1}^{n} p_j\gamma_j), \text{ and}$$

$$\text{(3b)} \qquad S = p_{n+1}x_{n+1} = \beta_{n+1}(y - \sum_{j=1}^{n} p_j\gamma_j).$$

Within the ELES, the demand for a commodity is composed of two parts. The first part (γ_i) is an amount which the consumer perceives as a "minimum requirement" or "habit persistence" quantity.[3] The second component consists of a proportion (β_i/p_i) of the income left after accounting for all expenditures on the habit persistence quantities. This income component is called "supernumerary" or "surplus" income. β_i is the marginal expenditure on the ith commodity, given a small change in income. Thus, depending upon the equation, β_i can be interpreted either as the marginal propensity to consume good i or the marginal propensity to save.

Ordinary price elasticity formulas are as follows:

Own Price

$$\varepsilon_{ii} = -1 + (1 - \beta_i)(\gamma_i/x_i)$$

Cross Price

$$\varepsilon_{ij} = -\beta_i(p_j\gamma_j/p_ix_i)$$

David B. Eastwood is an associate professor of consumer economics at the University of Tennessee, Knoxville. His work on the project was completed while on leave with the National Economics Division, Economics and Statistics Service, U.S. Department of Agriculture. John A. Craven is an agricultural economist, NED ESS USDA.

Views expressed do not necessarily reflect those of the USDA.

[1] Our model development is, of necessity, brief. The reader who is not familiar with the properties of complete demand systems in general, or the extended linear expenditure system in particular, can find an excellent discussion in Phlips.

[2] Both formulations are "extensions" of Stone's linear expenditure system (LES). They are extensions in the sense that savings are determined as an endogenous component in the model.

[3] Thus, Howe's assumption is that the minimum required quantity of savings is zero. The minimum requirement interpretation of the γ parameters is attributable to Samuelson.

The income elasticity formula is β_i/w_i, where w_i is the average budget share defined as p_ix_i/y. All variables are referenced at the current time period.

Variants of the ELES can be obtained by specifying alternative functional forms for the parameters. In addition to the form (3) which assumes constant values for the parameters, we specify a model in which the habit persistence parameters are assumed to be direct proportions of the previous period's consumption ($\gamma_i = \alpha_i x_{it-1}$).[4] For discussion purposes, we identify this model as ELESH. The solution of the ELESH utility maximization problem yields equations which are the same as time-subscripting the variables in (3a) and (3b) and substituting the proportional habit persistence formula for the γ_i's and γ_j's. We assume the marginal expenditure shares to be constant in both models.[5]

Properties of the Model

An advantage of specifying a particular utility function is that the theoretical properties of homogeneity, symmetry, and adding-up are automatically satisfied at each set of data coordinates. A disadvantage is that the properties inherent in the choice of a particular utility function may prove to be unduly restrictive. The Klein-Rubin utility function belongs to the additive class of utility functions—the marginal utility of each commodity is assumed to be independent of the level of consumption of all other commodities. Other implications inherent in this choice are that (*a*) $(x_i - \gamma_i) > 0$ for all observations, (*b*) $\beta_i > 0$ (no inferior goods), (*c*) $\sum_{i=1}^{n+1} \beta_i = 1$, (*d*) all goods must be substitutes, and (*e*) all price elasticities must lie within the range of zero and minus one. Thus, care must be taken to select commodities thought to possess these properties if the analysis is to be meaningful.

Procedure

Each model consists of twelve equations, eleven of which are consumption equations. Savings comprises the twelfth. Consumption categories are food-at-home, food-away-from-home, alcohol-tobacco, clothing, housing, utilities, transportation, medical, durables, nondurables, and "other" services. Major differences between our groupings and those contained in most published studies are the separation of the food component into at-home and away-from-home categories, the exclusion of alcohol from the food categories, the delineation of medical expenses into a separate category, and the transfer of automobiles from the transportation category into the durables category. A detailed composition of our demand categories can be found in Mann.

Data

Requisite data include quantities consumed, prices, and personal income. Our data source for the quantities and prices was the U.S. Department of Commerce's annual series on personal consumption expenditures. Quantities consumed were represented by personal consumption expenditures measured in constant (1972) dollars.[6] Our price data are implicit prices calculated as the ratio of personal consumption expenditures measured in current dollars to personal consumption expenditures measured in constant dollars. Income was measured as the sum of personal consumption expenditure on the eleven categories plus personal savings. Personal savings data were obtained from various issues of the *Survey of Current Business*.[7] All quantity and income data were placed on a per capita basis. Population data are midyear resident population figures obtained from *Population Estimates and Projections*.

We chose the 1955–78 time period for analysis. Considerations reflected in this choice include the desire to eliminate war years from the analysis and the recognition that the assumption of fixed-parameter values is probably suitable only for short time periods.

Parameter Estimation

In order to obtain parameter estimates, we used a nonlinear multivariate maximum-likelihood procedure developed and programmed by Snella (1979). Operationally, we appended an additive error term to the demand equations (3a) and estimated the parameters directly. The parameter of the savings equation (3b) was obtained by the property that the sum of the individual marginal propensities to consume plus the marginal propensity to save must equal one.

For the error specification, we assumed that $\mathbf{v}_t = \rho\mathbf{v}_{t-1} + \mathbf{e}_t$ where $\mathbf{v}_t$ is a vector of error terms and ρ is a common parameter for all equations. The vector $\mathbf{e}_t$ is assumed to have the following properties: $E(\mathbf{e}_t)$

[4] Our reason for specifying this model is that Pollak and Wales found this to be a particularly suitable hypothesis for the LES. To our knowledge, ELESH parameter estimates for the U.S. have not been published previously.

[5] Snella (1978) estimates a model for Norway in which the marginal expenditure shares are assumed to be functions of total expenditure. His assumption eliminates the linearity of the Engel curves assumed in (3). He concludes that "the hypothesis of constant uncommitted budget shares is not at all an implausible one, at least for the period of time analysed" (p. 297). We proceed under the assumption of constant marginal expenditure shares and, hopefully, minimize any misspecification by analyzing as short a time period as possible.

[6] These were aggregated from a detailed computer tape. The tape was obtained from Computer Systems and Services Division; Bureau of Economic Analysis; U.S. Department of Commerce.

[7] It should be pointed out that the sum of personal consumption expenditures on our eleven categories do not sum to "Total PCE" as reported in *Survey of Current Business*. We omit several reported items which do not pass through the marketplace. These are also detailed in Mann.

$= 0$, $E(e_t \mathbf{M}'_\tau) = 0$, all $\tau > t$; $E(\mathbf{e}_t \mathbf{e}'_\tau) = \delta_{t\tau}\Omega$, all t, all τ; $r(\Omega) = n$. Here E is the expectation operator, M is a vector of prices and income, δ is Kronecker's delta, r indicates the rank of a matrix, the prime indicates transposition, and the subscripts refer to a particular time period. The β, γ, and α values were not constrained to remain within the range of the a priori values.

Results

Parameter estimates for each system are presented in table 1. Each system solution is characterized by relatively high R^2 values and, in general, relatively small asymptotic standard errors for their estimated coefficients. Inspection of the table reveals that the estimated β values change according to model specification. The most pronounced changes are for the housing, medical, durables, "other" services, and savings categories. In general, the ELESH model allocates a larger proportion of surplus income to durables and savings—a smaller proportion is allocated to each of the remaining categories.

Associated with the small ELESH β estimates for housing and medical are α estimates, which exceed unity. This result gives rise to instability problems when the system is analyzed within a dynamic context. For these categories, the hypotheses $\beta_i = 0$, and $\alpha_i = 1$ cannot be rejected at the 10% level. The negative value for the medical β estimate is associated with habit persistence quantities which exceed actual consumption in all but two sample years. In part, these results may reflect some data peculiarities. The housing estimates may be affected by the inclusion of the imputed value of owner-occupied housing, which is contained in the national accounts. The medical category underwent very pronounced changes over the time period—its quantity increased in excess of 250% and its implicit price increased approximately 300%.

Further insight regarding the differences between the two forms can be obtained from inspection of table 2. Both models fit the data well overall, so it is not surprising to observe the similarity between the predicted expenditure columns. However, the surplus income columns show a marked discrepancy. As a percentage of income, the surplus increases from 21.6% in 1955 to 54.3% in 1978 for the ELES; whereas, the corresponding figures for the ELESH are, respectively, 24.5 and 22.9. Relative to income, the ELESH form has the surplus falling because consumers are increasing their habit persistence quantities. This is consistent with the notion people have of a rising standard of living while at the same time not feeling any better off.

Predicted savings in both models provide fairly close approximations of actual savings, and examination of the data provides some basis for ELESH being superior. Of the twelve actual turning points, ELES correctly predicts four; whereas, ELESH correctly predicts seven. ELESH's predicted savings values are closer to the actual values in thirteen of the twenty-four years. Unfortunately, both models greatly overpredict savings in the last three years.

Focusing on the food demand equations, the systems imply different patterns for the habit persistence quantities. The ELES γ estimate for food-at-home was 96% of consumption in 1955 and trended downward to 78% in 1978. For the ELESH the corresponding figures were 91% and 95%, respectively, with no discernable trend. A similar pattern was observed for the food-away-from-home habit-persistence quantities expressed as a percentage of consumption. For the ELES, this was 82% in 1955 and trended to 60% in 1978. For the ELESH, the corresponding figures are approximately 87% for both years.

System projections for the food demand categories, along with their observed values, are presented in table 3. The ELES appears to project food demand better than does the ELESH. The ELES projects the magnitude of demand for food-at-home better than the ELESH for fourteen out of the twenty-four sample years. ELES also identifies four out of nine turning points versus two for

Table 3. Food at Home and Food Away from Home: Actual Observations and System Projections

[a] ELESH computations are bracketed; ELES are placed above.

ELESH. For food-away-from-home, both systems identify four out of eight turning points, but the ELES projects the quantity demanded better in the early years.

Uncompensated price, total expenditure, and income elasticities for the two models are presented in table 4. There are too many to discuss individually. Starting with the ELES values, the own-price elasticities for food-at-home, and alcohol and tobacco are the most inelastic. The demand for food-away-from-home is more sensitive to its price than food-at-home, which is consistent with the latter being more a necessity. Durables has the elasticity closest to −1. Four luxury goods are indicated by the income elasticities (medical, durables, nondurables, and savings). The demand for food-at-home appears to be the least sensitive to other prices as the uncompensated cross-price elasticities of the first row are the closest to zero of all the rows. Food-at-home prices have the largest effects on the quantities demanded of the other goods. This is indicated by the uncompensated cross-price elasticities of the first column, which are the smallest of the columns. The food-at-home price is observed also to have the largest impact on savings.

The ELESH model has elasticities which indicate somewhat different responses. All of the own-price elasticities are more inelastic than their ELES counterparts, thereby indicating less own-price sensitivity. Housing now is the most inelastic, followed by alcohol and tobacco and food-at-home. This is consistent with the smaller increases in ELESH surplus income. Most of the current period's income in ELESH is used as habit persistence. Uncompensated cross-price elasticities do not display uniform change vis-à-vis those of the ELES, but within the ELESH a pattern similar to that of ELES emerges. The cross-price elasticities of housing are now the lowest, followed by food-at-home. The food-at-home column, except for housing, is the smallest. There are only two luxuries in ELESH. They are durables and savings.

Summary

Two forms of the extended linear expenditure system were estimated. Both include savings as a budget category so that consumer responses can be analyzed across the entire spectrum of decision making. Other features of the study are (*a*) the delineated demand categories differ from those traditionally used, and, we feel, are more relevant to the study of current economic problems, (*b*) ELESH parameter estimates for the United States have not been published previously, and (*c*) the models account for first-order autocorrelation.

The model form was found to have important implications for the analysis of consumer responses. Surplus income rose dramatically in ELES; whereas, it actually declined as a percentage of disposable income in ELESH. The latter is more consistent with the phenomenon of consumers experiencing a rising standard of living but not really feeling better off. Both models predict savings well, but ELESH has a small advantage overall. ELES projects food demand better then ELESH. This suggests that, for the food categories, the fixed-habits assumption is more plausible than the adaptive habits hypothesis.

Larger income elasticities are obtained for ELES. Except for durables, ELESH own-price elasticities lie closer to zero than those for ELES. This suggests that for ELESH, consumer demand is less responsive to own-price changes. It is due, in part, to the lower values obtained for the ELESH marginal budget shares, but the major part is due to the higher levels of habit persistence quantities in ELESH. The cross-price elasticities suggest that, *ceteris paribus*, a change in the price of food-at-home has larger percentage effects on the quantities demanded in the other categories than vice versa.

Evaluating Price Stabilization Schemes with Mathematical Programming

Peter B. R. Hazell and Carlos Pomareda

Price stabilization schemes for risky agricultural markets continue to attract interest. Applied welfare economics has offered some insights into who gains from stabilization (Turnovsky). Economic models, such as stochastic simulation and dynamic programming, have been used to evaluate the costs of alternative stock sizes and storage rules (Reutlinger; Burt, Koo, Dudley).

A limitation of these analytical approaches is their difficulty in dealing with substitutes on the demand side and/or competition for scarce resources with other commodities in production. Stabilization interventions in any one market may have important spillover effects in other markets that are not captured in the usual single-commodity framework. In addition, even though the importance of producers aversion to price and yield risks has been recognized as a determinant of supply (Just), the implied changes in average supply following price stabilization typically are ignored. Also, nearly all the analytical work on price stabilization has focused on a very narrow set of policy objectives, particularly the changes in producers' and consumers' surplus, producers' income, and storage costs. However, price stabilization may affect a wider range of policy issues when allowance is made for risk response and multimarket interactions.

Price-endogenous mathematical programming models can take account of multiproduct relationships in supply and demand and can simulate the effects of risk-averse behavior at the farm level. They also can provide a wealth of detailed information about production, resource use, consumption, prices, and trade, at both the micro (farm or regional) and sectorwide levels. This paper shows how a class of price-endogenous mathematical programming models that assume integrability of product demands can be used to evaluate price stabilization schemes.[1] The method is illustrated by using an agricultural sector model of Guatemala to evaluate a hypothetical bean price stabilization scheme.

An Agricultural Sector Model of Guatemala

The Guatemalan model used here is typical of the price-endogenous mathematical programming models recently reviewed by McCarl and Spreen. In particular, the model has a linear and integrable demand system, a linear constraint set, and a risk behavior specification of the mean standard deviation type. The model is fully described in Pomareda. The purposes here are simply to establish notation and to review those model features necessary for discussing some price stabilization experiments.

Let the domestic demand system be $\mathbf{P} = \mathbf{A} - \mathbf{B}\mathbf{P}$, where $\mathbf{P}$ and $\mathbf{Q}$ are $n \times 1$ vectors of domestic prices and market supplies, respectively, and $\mathbf{A}$ and $\mathbf{B}$ are $n \times 1$ and $n \times n$ matrices of demand coefficients. For notational simplicity we ignore representative farm subscripts and assume international trade in all commodities. In fact, trade activities are included in the model only to permit food crop imports and nonfood crop exports. These restrictions closely approximate past Guatemalan trade policies, and can lead to important differences between domestic and world prices.

The model objective function that provides the competitive solution to prices and quantities in all markets is:

$$(1)\quad \text{MAX } \Phi = E(\mathbf{Q}')\,[\mathbf{A} - \tfrac{1}{2}\,\mathbf{B}E(\mathbf{Q})] - \mathbf{C}'_x\mathbf{X} + \mathbf{C}'_r\mathbf{R} - \mathbf{C}'_m\mathbf{M} - k(X'\Omega\mathbf{X})^{\frac{1}{2}},$$

where $E(\mathbf{Q}) = E(\mathbf{N})\mathbf{X} + \mathbf{M} - \mathbf{R}$, and $\mathbf{X}$ is an $n \times 1$ vector of crop acreages grown; $\mathbf{N}$ is an $n \times n$ diagonal matrix of stochastic per acre yields; $\mathbf{M}$ and $\mathbf{R}$ are $n \times 1$ vectors of tons of imports and exports, respectively; $\mathbf{C}_x$ is an $n \times 1$ vector of production costs per acre; $\mathbf{C}_m$ is an $n \times 1$ vector of import costs per ton; $\mathbf{C}_r$ is an $n \times 1$ vector of export prices per ton net of export costs; Ω is an $n \times n$ covariance matrix of crop revenues (prices times yield);[2] and k is a suitable average of individual farmers' risk-aversion parameters. This maximand is only applicable if $\mathbf{B}$ is symmetric (the integrability requirement). In the absence of estimates of cross-price

Peter Hazell is a Research Fellow at the International Food Policy Research Institute in Washington, D.C., and Carlos Pomareda is a Research Economist at the Inter-American Institute of Agricultural Sciences in Costa Rica.

The views expressed in this paper are those of the authors, and should not necessarily be attributed to the institutions with which they are affiliated.

[1] Integrability of product demand requires that the cross-price effects are equal over all commodity pairs. Relaxation of this assumption requires more difficult model solution procedures—such as linear complementarity programming (Takayama and Judge)—and the producer and consumer surplus measures used in this paper no longer would be applicable.

[2] We assume $\mathbf{C}_x$, $\mathbf{C}_r$ and $\mathbf{C}_m$ are not stochastic; hence the variance of income and total revenue are identical.

effects, the **B** matrix is specified as diagonal in the Guatemalan model.

As Hazell and Scandizzo (1974) have shown, the maximand (1) provides the market equilibria that would be arrived at if production is lagged and farmers act on the basis of price expectations that are formed independently of their expectations about yields. Such market equilibria are socially inefficient (Hazell and Scandizzo 1975). However, if producers act on the basis of revenue expectations, thereby taking account of any correlations between prices and yields, socially efficient market equilibria are attained. The maximand,

$$(2)\quad \text{Max } \theta = E[\mathbf{Q}'(\mathbf{A} - \tfrac{1}{2}\mathbf{BQ})] - \mathbf{C}'_x\mathbf{X} - \mathbf{C}'_r\mathbf{R} - \mathbf{C}'_m\mathbf{M} - k(\mathbf{X}'\Omega\mathbf{X})^{\frac{1}{2}} = \Phi - \tfrac{1}{2}\Sigma_i\Sigma_j X_i X_j \sigma_{ij} b_{ij},$$

where σ_{ij} denotes the covariance between the yields of the ith and jth crops, provides the socially preferred equilibrium solution (Hazell and Scandizzo 1977).

The covariance matrix of crop revenues is treated as a constant by Hazell and Scandizzo and is typically estimated on the basis of time-series data on prices and yields. While observed price and yield deviations around their mean (or trend lines) may be an acceptable measure of risk in market equilibrium, the revenue elements of Ω are not invariant with respect to their mean prices.[3] Thus, if the expected prices in the equilibrium solution are different from the sample mean prices used in the calculation of Ω, then Ω should be revised. Procedures for endogenizing the Ω matrix have not yet been developed; therefore, in the Guatemalan model, we used an iterative procedure. If, at the tth iteration the i, jth element of Ω had mean prices $\bar{P}_{it}$ and $\bar{P}_{jt}$, and these differed from the equilibrium prices $E(P_{it})$ and $E(P_{jt})$ obtained in the corresponding tth model solution, then $E(P_{it}) - \bar{P}_{it}$ and $E(P_{jt}) - \bar{P}_{jt}$ were added to the sample price observations for the ith and jth crops, ω_{ij} was recalculated, and a new solution was obtained. This procedure was repeated until $E(P_{it}) - \bar{P}_{it}$ and $E(P_{jt}) - \bar{P}_{jt}$ converged to approximately zero. In practice, Ω typically converged in three or four iterations.

Methodology of Price Stabilization Experiments

We are interested in a stabilization scheme in which the domestic price of beans is fixed at its expected market equilibrium value. Such price stabilization would be achieved through the establishment of buffer stocks. To assure a self-liquidating stock on average, the price at which a market is to be stabilized is the expected market clearing price in equilibrium. This price can be obtained from the model. The problem is to modify the model to obtain the market equilibrium solution corresponding to the stabilized situation.

The model solutions are conditioned in part by the covariance matrix Ω, and stabilizing the price of the jth crop changes the variance and the covariance terms involving that crop. An important part of the method of experimenting with price stabilization therefore follows: one must recalculate all the relevant elements of Ω using the stabilized price $\bar{P}_j = E(P_j)$ and then resolve the model for a new equilibrium.

However, producers will adjust their cropping patterns to arrive at a new optimal plan, given their assumed E, σ utility functions. This is the risk-response effect induced by stabilization, and the original expected market-clearing price for the stabilized crop no longer will be the same. The stabilized price, $\bar{P}_j = E(P_j)$, now will have to be revised to retain a self-liquidating buffer stock, the element of Ω recalculated, and the solution process repeated. This iterative procedure is repeated until Ω converges.

As will later become clear, a small modification is also required in the demand specification for the stabilized crop in equation (2). Q_{jt} is no longer stochastic when the stabilizing agency sells a fixed amount $\bar{Q}_j$ to consumers each year; and equation (2) must be revised so that $E(Q_j^2) = \bar{Q}_j^2$ for the stabilized commodity. This can be done by setting $\sigma_{ij} = 0$, all i, in equation (2).

The poststabilized solution provides the expected values of all activities in the new market equilibrium. Any changes from the prestabilized solution stem from supply adjustments following changes in farm-levels risk, or from the disappearance of the covariance between price and yield leading to identical revenue and price expectations for the stabilized crop. Assuming producers were risk-neutral ($k = 0$) and that they plan on the basis of price expectations (objective function [1]), then the pre- and poststabilized solutions would in fact be identical, with $\bar{P}_j$ remaining constant. Even though the model activity levels would not change under these conditions, the removal of price and market supply variations still leads to changes in the expected values of the consumers' surplus, producers' surplus, and income.

The surplus and income changes can be calculated in the model. Given our assumed market structure, prices in the tth year are given by $\mathbf{P}_t = \mathbf{A} - \mathbf{BQ}_t$. Expected consumers' surplus in the prestabilized situation is

$$(3)\quad E(W_c) = E[\mathbf{Q}'_t(\mathbf{A} - \tfrac{1}{2}\mathbf{BQ}_t) - \mathbf{P}'_t\mathbf{Q}_t], = \tfrac{1}{2}E(\mathbf{Q}'\mathbf{BQ}).$$

Expected producers' surplus is

$$(4)\quad E(W_p) = E[\mathbf{Q}'(\mathbf{A} - \mathbf{BQ})] - \mathbf{C}'_x\mathbf{X} + \mathbf{C}'_r\mathbf{R} - \mathbf{C}'_m\mathbf{M} - \mathrm{k}(\mathbf{X}'\Omega\mathbf{X})^{\frac{1}{2}},$$

where we have used an *ex post* measure of the surplus, that is, actual revenue less the *ex ante*

[3] Let $P^*_j = P_j + \lambda$ with λ constant, then $\text{Cov}(P^*_j n_j, P_i n_i) = \text{cov}(P_j n_j, P_i n_i) + \lambda \text{Cov}(n_j, P_i n_i)$.

costs of production incurred at the time when **X** is planted (Hazell and Scandizzo 1975).

The producer's surplus is defined net of the risk term $k(\mathbf{X}'\,\Omega\,\mathbf{X})^{\frac{1}{2}}$, which is the income compensation producers require for accepting the risks associated with **X**. By deleting this term in equation (4), the expected value of producers' income in the prestabilized markets is obtained.

To measure aggregate social welfare, we take a common approach and measure expected social welfare as the sum of the expected producers' and consumers' surplus. In the prestabilized market, this is the sum of equations (3) and (4) and is equal to model objective function (2). This welfare interpretation of (2) provides the rationale for the social efficiency of revenue expectations (Hazell and Scandizzo 1975, 1977).

The establishment of a buffer stock agency stabilizes the prices of a subset of the vector $\mathbf{P}_t$. By partioning the relevant matrices, the price and quantity vectors are

$$(5)\qquad \begin{pmatrix}\mathbf{P}_{1t}\\ \mathbf{P}_{2t}\end{pmatrix} = \begin{pmatrix}\mathbf{A}_1\\ \mathbf{A}_2\end{pmatrix}\begin{pmatrix}\mathbf{B}_{11} & \mathbf{B}_{12}\\ \mathbf{B}_{21} & \mathbf{B}_{22}\end{pmatrix}\begin{pmatrix}\mathbf{Q}_{1t}\\ \mathbf{Q}_{2t}\end{pmatrix}, \text{ and}$$

$$(6)\qquad \begin{pmatrix}\mathbf{Q}_{1t}\\ \mathbf{Q}_{2t}\end{pmatrix} = \begin{pmatrix}\mathbf{N}_{1t} & 0\\ 0 & \mathbf{N}_{2t}\end{pmatrix}\begin{pmatrix}\mathbf{X}_1\\ \mathbf{X}_2\end{pmatrix} + \begin{pmatrix}\mathbf{M}_1\\ \mathbf{M}_2\end{pmatrix} - \begin{pmatrix}\mathbf{R}_1\\ \mathbf{R}_2\end{pmatrix}.$$

If the buffer stock agency wishes to stabilize prices $\mathbf{P}_1$ at $\bar{\mathbf{P}}_1$, where $\bar{\mathbf{P}}_1$ is the vector of prices that ensure self-liquidating stocks on average, the agency would plan to buy all the production of $\mathbf{Q}_1$ each year and, by controlling imports $\mathbf{M}_1$ and exports $\mathbf{R}_1$, to release the quantities of $\mathbf{Q}_1$ to the domestic market each year that are required to maintain prices at $\bar{\mathbf{P}}_1$. If $\mathbf{Q}_1$ and $\mathbf{Q}_2$ are demand-independent groups (that is, $\mathbf{B}_{21} = \mathbf{B}_{12} = 0$), the agency trades constant amounts $\bar{\mathbf{M}}_1$ and $\bar{\mathbf{R}}_1$ each year and sells constant amounts $\bar{\mathbf{Q}}_1 = E(\mathbf{N}_1)\mathbf{X}_1 + \bar{\mathbf{M}}_1 - \bar{\mathbf{R}}_1$ to the domestic market.[4] When $\mathbf{Q}_1$ and $\mathbf{Q}_2$ are not demand independent, $\mathbf{P}_1$ is subject to random variations arising from $\mathbf{Q}_2$ as well as from variations in $\mathbf{Q}_1$. Since the agency would not carry stocks of $\mathbf{Q}_2$, the actual quantities of $\mathbf{Q}_1$ sold would have to be varied from year to year to compensate for variations in $\mathbf{Q}_2$. $\bar{\mathbf{Q}}_1$ would then denote only the expected value of the amounts sold by the agency to maintain prices at $\bar{\mathbf{P}}_1$.

Where $\bar{\mathbf{Q}}_1$, $\bar{\mathbf{M}}_1$ and $\bar{\mathbf{R}}_1$ are not stochastic, the expected consumers' and producers' surplus in the stabilized situation are

$$(7)\qquad E(W_c) = \tfrac{1}{2}\bar{\mathbf{Q}}'_1\mathbf{B}_{11}\bar{\mathbf{Q}}_1 + \tfrac{1}{2}E\,[\mathbf{Q}'_2\mathbf{B}_{22}\mathbf{Q}_2],$$

$$(8)\qquad E(W_p) = \bar{\mathbf{Q}}_1'\,(\mathbf{A}_1 - \mathbf{B}_{11}\bar{\mathbf{Q}}_1) + E\,[\mathbf{Q}'_2(\mathbf{A}_2 - \mathbf{B}_{22}\mathbf{Q}_2] - \mathbf{C}'_xX - \mathbf{C}'_m\mathbf{M} + \mathbf{C}'_r\mathbf{R} - k\,(\mathbf{X}'\mathbf{\Omega}\mathbf{X})^{\frac{1}{2}},$$

and expected producers' income is equation (8) with the risk term $k\,(\mathbf{X}'\mathbf{\Omega}\mathbf{X})^{\frac{1}{2}}$ omitted.

Taking the sum of equations (7) and (8), expected social welfare in the stabilized situation is

$$(9)\qquad E(W) = \bar{\mathbf{Q}}'_1\,(\mathbf{A}_1 - \tfrac{1}{2}\mathbf{B}_{11}\bar{\mathbf{Q}}_1) + E[\mathbf{Q}'_2(\mathbf{A}_2 - \tfrac{1}{2}\mathbf{B}_{22}\mathbf{Q}_2)] - \mathbf{C}'_x\mathbf{X} - \mathbf{C}'_m\mathbf{M} + \mathbf{C}'_r\mathbf{R} - k\,(\mathbf{X}'\mathbf{\Omega}\mathbf{X})^{\frac{1}{2}}.$$

Equation (9) is a modified version of (2) in which $E(Q_j^2)$ is replaced by $\bar{Q}_j^2$ for all stabilized commodities. It is also the relevant model maximand for obtaining the market equilibria corresponding to revenue-forecasting behavior in the stabilized situation. Because prices and yields are no longer correlated for the stabilized commodities, producers act as price forecasters when planning $\mathbf{X}_1$ and as revenue forecasters when planning $\mathbf{X}_2$.

The gain in expected social welfare from stabilizing $\mathbf{P}_1$ is the value of equation (9) minus equation (2). If producers are risk-neutral and plan on the basis of price forecasts, the values of **X**, **M**, and **R** remain constant; $\bar{\mathbf{Q}}_1$ equals $E\,(\mathbf{Q}_1)$ of the prestabilized situation; and the welfare gain is

$$(10)\qquad E(\Delta W) = \tfrac{1}{2}\,[E\,(\mathbf{Q}'_1\mathbf{B}_{11}\mathbf{Q}_1) - \bar{\mathbf{Q}}'_1\mathbf{B}_{11}\bar{\mathbf{Q}}_1] = \tfrac{1}{2}\,\Sigma_i\Sigma_j X_{1i}\,X_{1j}\sigma_{1ij}b_{1ij}.$$

To obtain the values of the surplus and income measures defined above, it is only necessary to incorporate equations (1), (2), and (4) into the model and to have access to the value of $k\,(\mathbf{X}'\mathbf{\Omega}\mathbf{X})^{\frac{1}{2}}$ from the solution. Since either (1) or (2) would be the model maximand, then only two additional accounting rows are required. These are quadratic equations, but they can be linearized concurrently with the objective function (Duloy and Norton).[5]

So far all the activity levels **X**, **M**, and **R** are treated as nonstochasic. Because **X** (the crop areas planted) depends in part on producers' forecasts about prices, it is implied that producers hold constant forecasts over time. In reality, forecasts about prices do change from year to year even when the markets are in equilibria and **X**, **R**, and **M** are stochastic.

If the assumption of nonstochastic activities is relaxed, the surplus and income measures used in the model will be incorrect. To derive the correct results, consider the generalized supply structure:

$$\mathbf{Q}_t = \mathbf{N}_t\mathbf{X}_t + \mathbf{M}_t - \mathbf{R}_t,$$

where t subscripts denote activities that are

[4] Complications arise when a stabilized commodity is traded at uncertain prices. The agency must then have the financial facilities to stabilize these prices for the domestic market. Fortunately this problem does not arise with beans in Guatemala because they are not traded.

[5] Linearization of (2) and (4) proved especially easy in the Guatemalan model because **B** is diagonal. In this case.

$$E\,[\mathbf{Q}'(\mathbf{A} - \tfrac{1}{2}\mathbf{B}\mathbf{Q})] = E(\mathbf{Q}')\,[\mathbf{A} - \tfrac{1}{2}\mathbf{B}\mathbf{M}E(\mathbf{Q})],$$

where **M** is a diagonal matrix with jth diagonal element $m_j = E(n_j^2)/E(n_j)^2 = 1 + R_j^2$, and R_j is the coefficient of variation of the yield of the jth crop. Since **M** is a constant, then **BM** can be calculated as part of the input to the model. The matrix **BM** remains diagonal, and the term $E(\mathbf{Q}')\,[\mathbf{A} - \tfrac{1}{2}\mathbf{B}\mathbf{M}\,E(\mathbf{Q})]$ can be linearized using the Duloy-Norton method. Note that m_j must be equated to unity for stabilization experiments on the jth crop.

stochastic over time. We also assume that trade is undertaken at uncertain prices.

Expected social welfare in period t in the pre-stabilized situation is now:

$$E(W) = E[\mathbf{Q}'(\mathbf{A} - \tfrac{1}{2}\mathbf{BQ})] - \mathbf{C}'_x E(\mathbf{X}) - E(\mathbf{C}'_m)E(\mathbf{M}) + E(\mathbf{C}'_r)E(\mathbf{R}) - kV(\mathbf{r}'\mathbf{X})^{\frac{1}{2}} + F,$$

where $F = \Sigma_j [\mathrm{cov}(C_{rj}, R_j) - \mathrm{cov}(C_{mj}, M_j)]$ and $V(\mathbf{r}'\mathbf{X})$ denotes the variance of total revenue. Now,

$$V(\mathbf{r}'\mathbf{X}) = V(\Sigma_j r_j X_j) = \Sigma_i \Sigma_j [E(X_i X_j r_i r_j) - E(X_i r_i)\, E(X_j r_j)],$$

which after some expansion yields

$$V(\mathbf{r}'\mathbf{X}) = E(\mathbf{X}')\Omega E(\mathbf{X}) + G,$$

where

$$G = \Sigma_i \Sigma_j [\mathrm{Cov}(X_i X_j, r_i r_j) + \mathrm{Cov}(X_i, X_j)E(r_i r_j) - \mathrm{cov}(X_i, r_i)E(X_j r_j) - E(X_i)E(r_i)\,\mathrm{cov}(X_j, r_j)].$$

Letting D denote $E(\mathbf{X}')\boldsymbol{\Omega}E(\mathbf{X})$, then a Taylor expansion of $V(\mathbf{r}'\mathbf{X})^{\frac{1}{2}} = (D + G)^{\frac{1}{2}}$ around D provides

$$V(\mathbf{r}'\mathbf{X})^{\frac{1}{2}} = D^{\frac{1}{2}} + \Sigma_s g_s(D)G^s,$$

where $g_1(D) = \frac{1}{2}D^{-\frac{1}{2}}$, $g_2(D) = -1/8D^{-3/2}$, and so forth.

Collecting terms, expected social welfare is

$$(11)\quad E(W) = \{E[\mathbf{Q}'(\mathbf{A} - \tfrac{1}{2}\mathbf{BQ})] - \mathbf{C}'_x E(\mathbf{X}) - E(\mathbf{C}'_m)E(\mathbf{M}) + E(\mathbf{C}'_r)E(\mathbf{R}) - k[E(\mathbf{X}')\boldsymbol{\Omega}E(\mathbf{X})]^{\frac{1}{2}}\} + F - k[\Sigma_s g_s(D)G^s].$$

The terms in the curled parentheses of (11) are equivalent to the value of $E(W)$ defined in (2), the only difference being that the activity levels are now defined as expected values. However, whereas (2) correctly measures expected social welfare when the activity levels are nonstochastic, it is now necessary to evaluate the additional terms F and $\Sigma_s g_s(D)G^s$. All the terms in F and G become zero if $\mathbf{X}$, $\mathbf{R}$, and $\mathbf{M}$ are nonstochastic; therefore, their omission from (2) is justified.

$\mathbf{X}$ is stochastic because producers adjust their cropping patterns each year according to changes in their forecasts about prices. When the price vector $\mathbf{P}_1$ is stabilized at $\bar{\mathbf{P}}_1$, $\mathbf{X}_1$ becomes nonstochastic. The buffer stock agency also takes control of all importing and exporting activities for $\mathbf{Q}_1$, and $\mathbf{M}_1$ and $\mathbf{R}_1$ are stabilized at $\bar{\mathbf{M}}_1$ and $\bar{\mathbf{R}}_1$. As such, all covariance terms in F and G associated with activities in the vectors $\mathbf{X}_1$, $\mathbf{M}_1$, and $\mathbf{R}_1$ become zero with stabilization, and the expected value of social welfare in the stabilized situation is equation (9) $+ F - k\,\Sigma_s g_s(D)G^s$, where F and D contain only the relevant covariances.

Estimates of the gain in social welfare from price stabilization based on equations (2) and (9) could be misleading if changes in F and $\Sigma_s g_s(D)G^s$ are large. There is no basis for calculating these terms in a mathematical programming model, but some indication of their value can be obtained from time-series data.

A similar analysis of the expected producers' surplus leads to a generalized form of (4) in which the terms $F - k\,\Sigma_s g_s(D)G^s$ are added. The consumers' surplus is not affected.

The Guatemalan Experiments

Table 1 contains some basic foodcrop results obtained from the model, together with actual data for 1976, the year for which the model was numerically specified.[6] The results are presented for price-and revenue-forecasting behavior (using model maximands (1) and (2), respectively) and for three different levels of risk aversion. A k value of zero implies risk neutrality; k values of 1.65 and 3.16 represent "reasonable" and "extreme" levels of risk aversion, respectively. Specifically, k values of 1.65 and 3.16 correspond to producers' maximizing the 0.05 and 0.001 percentiles of their income distributions, providing these are normally distributed (Baumol).[7]

The results in table 1 suggest that the model describes 1976 production levels quite well. They are

[6] The model also includes coffee, sugar, cotton, and domestic and export bananas, but the production of these crops was insensitive to the experiments reported here.

[7] On the basis of a chi-square test of detrended time-series data, it was not possible to reject the null hypothesis that incomes were normally distributed.

[b] Corrected for stochastic activity levels.

consistent with an assumption of "reasonable" risk behavior ($k = 1.65$). The results obtained for price and revenue expectations are similar for given values of k. As risk aversion increases, bean production is significantly curtailed. Beans are clearly a high-risk crop and a suitable candidate for illustrative price stabilization experiments.

Price stabilization cannot affect the model's activity levels if producers are risk neutral and plan on the basis of price expectations, but it does lead to a small gain in uncorrected social welfare of about $5 million. The more interesting results for k values of 1.65 and 3.16 are summarized in table 2. Surplus measures are reported as obtained from the model and after correcting for stochastic variation in activity levels, as measured from time-series data.

Price stabilization for beans leads to an uncorrected gain in social welfare of about $12 million when $k = 1.65$. When corrected for observed variations in X over time, the gain is much smaller; it is $4 million and $1.2 million, respectively, for price and revenue expectations behavior. The uncorrected gain is almost $15 million when $k = 3.16$, but it is essentially zero when the necessary corrections are made. If our calculations are correct, producers in Guatemala appear to be adjusting their cropping patterns each year in a manner that is socially efficient. Stabilizing the bean price would do little to improve their efficiency.

There are other effects from stabilizing bean prices. When $k = 1.65$, bean production increases by 4.3% and 9% for price and revenue expectations, respectively. This additional output is produced with resources that otherwise would be idle.[8] There is also a sizeable decline in the standard deviation of producers' income. In both cases, the domestic price declines substantially, and there is an increase in agricultural employment, of 17,000 jobs in the case of price expectations, and of 33,000 jobs with revenue expectations. The gains are more exaggerated under extreme risk aversion, and bean production more than doubles. However, because beans are imported in the prestabilized solution for this value of k, the extra production largely substitutes for imports. This leads to a decline in the domestic price of only 13%. The agricultural trade balance is affected favorably, and the large increase in bean production leads to a decrease in maize and rice production and an increase in the standard deviation of producers' income.

The results in table 2 show some ambiguity in the gain to producers and consumers. Consumers gain from bean price stabilization when $k = 1.65$, but lose when $k = 3.16$. Average producers' income increases when they hold price expectations (by 2.3% and 17% for k values of 1.65 and 3.16, respectively) but declines when they plan on the basis of revenue expectations.

[8] Production is modelled by three different farm sizes representing primarily subsistance farms, market-oriented farms which rely predominantly on family labor, and large commercial farms which use hired labor and produce most of the traditional export crops. The middle-sized farms have some idle land and labor resources in the model solution (which accords well with available evidence), and these resources are utilized more fully in the model when bean prices are stabilized.

Conclusions

Price-endogenous mathematical programming models are proposed in this paper as useful tools for analyzing price stabilization policies. Their particular attractions for this purpose are that they (a) take explicit account of interactions between commodities in supply and demand, (b) can incorporate risk-averse behavior and simulate the supply response effects of stabilization policies, (c) can produce much information about wider impacts of price stabilization, and (d) are relatively easy to solve, especially when linearized.

The main limitation of the approach is that it cannot be used to derive storage costs or to analyze effects of various stock sizes. Although the analysis proposed here assumes that prices are stabilized at a single value, the method does provide a useful technique for a first round of analysis which might be supplemented later with other simulation techniques.

Foreign Competition and Trade Policy for the Florida Lime Industry

Emilio Pagoulatos, J. Scott Shonkwiler, and Robert L. Degner

The Florida fresh lime industry recently has faced increasing competition from imports, particularly from Mexico. Concern about increased lime imports began in the mid-1970s and has focused on their potentially adverse effect on Florida prices and production. In order to evaluate the potential threat of foreign competition on Florida's lime industry and the trade policy alternatives, quantitative estimates are needed of the impact of imports on the industry.

The purpose of this paper is to estimate the effects of import competition and alternative trade policies on the Florida lime industry (Andrew, DeBoon, McPherson; Freebairn and Rausser; Novakovic and Thompson; Salathe, Dobson, Peterson). The methodology involves specifying and estimating an econometric model of the Florida lime and U.S. trade sectors. A set of reduced-form equations is derived from the simultaneous equation model. The estimated multipliers are used to measure the impacts of alternative U.S. tariff and quota policies on lime imports, Florida lime production, and prices.

Florida's Fresh Lime Industry

Florida and California are the only two states in the United States producing limes commercially (Degner and Rooks; Degner, Shonkwiler, Cubenas.) Since the early 1970s, Florida has accounted for about 90% of the domestic lime acreage and California the remaining 10%.

Imports have increased steadily since 1972–73, when they constituted only 4% of U.S. fresh lime supply. By 1976–77, however, imports accounted for about 15%. In the 1977–78 season, imports represented approximately one-third of U.S. fresh lime supplies, and in the 1979–80 season, over 37%. Fresh limes are protected in the United States by a specific tariff (TSUS item no. 147.22) of one cent per pound. In recent years the ad volorem equivalent of this tariff has been about 7%.

Although a number of Caribbean countries export fresh limes to the United States, Mexico is the dominant source. Mexico has almost 112,000 acres of limes, compared with Florida's 4,600. Although a high proportion of Mexico's acreage is the seeded Mexican lime used for essential oil production, production of Persian limes, the preferred fresh market variety grown by Florida producers, is increasing.

The Economic Model

The main components of the model are the foreign trade sector and the Florida market for limes. This allows the simultaneous determination of import and export prices, import levels, and the quantity and price of Florida limes.

Following Magee and Goldstein and Khan, we specify the foreign trade sector to include the supply of lime exports from Mexico (M^s), the U.S. demand for lime imports (M^d), and the relative price equation to link the U.S. import price (PM) with the Mexican export price (PX).

In the absence of export tariffs, we specify the export supply of limes from Mexico as a function of the export price (in pesos), real income in Mexico ($YMEX$), and the lagged export price:

$$(1) \qquad M_t^s = f(PX_t, YMEX_t, PX_{t-1}).$$

Current and lagged export prices are expected to be positively related to exports. As export prices rise, production for export becomes more profitable, and allocation to the export market increases. However, as income rises in the exporting country, domestic demand for the product rises, and *ceteris paribus*, exports decline.

The import demand for limes is specified as follows:

$$(2) \qquad M_t^d = g(PM_t, QF_t, YUS_t, CPI_t),$$

where PM is the import price (in dollars), QF is the quantity of limes marketed by Florida producers, YUS is the U.S. income level, and CPI is the U.S. consumer price index (Leamer and Stern, pp. 8–17). It is hypothesized that the U.S. demand for imported limes is negatively related to import price and positively related to consumer income. In addition, Florida marketings should exert a negative influence on imports. Equation (2) also reflects the hypothesis that as the price of all other consumer goods (CPI) rises, *ceteris paribus*, the import demand increases.

Emilio Pagoulatos is an associate professor, and J. Scott Shonkwiler and Robert L. Degner are assistant professors in the Food and Resource Economics Department, University of Florida.

Comments by Kary Mathis and two anonymous reviewers are gratefully acknowledged.

Finally, the following identities complete the specification of the foreign trade sector:

$$PM_t = \frac{1}{r_t} PX_t + T, \quad \text{and} \tag{3}$$

$$M_t^s = M_t^d. \tag{4}$$

Expression (3) relates the dollar-valued import price (PM) to the peso-valued export price received by Mexican suppliers. This identity explicitly introduces the foreign exchange rate (r = pesos/dollar) and the U.S. specific tariff rate (T = \$.01/lb.). Expression (4) imposes a market-clearing solution on the trade side of the model.

With regard to the domestic side of the model, the specification of the Florida lime supply function is

$$QF_t^s = h\Big(\sum_{i=1}^{k} PF_{t-i}, \sum_{i=1}^{m} PPF_{t-i}, FW_t, QF_{t-1}, TIME\Big), \tag{5}$$

where PF is the Florida lime price, PPF represents prices paid by growers for the purchase of production inputs, FW is a variable denoting Florida weather conditions, and $TIME$ is an annual trend term. Given the perennial nature of limes, no attempt was made to include alternative crop prices in the supply equation.

The lags on product and input prices account for the influence of expected prices and costs on supply due to the time lapse between planting and output. French and Matthews recognize that, for perennial crops, "producers might consider experience over several years as a better indicator of expected profitability" (p. 484). Lime prices should exert a positive impact on supply, while prices paid by farmers should negatively affect supply. Lagged lime output was included in the specification to capture partial production adjustments, and it is expected that $0 < \partial h/\partial QF_{t-1} < 1$. Finally, the time trend represents the effects of omitted variables, such as technological change, that have exerted systematic effects over time.

The quantity of Florida limes demanded is postulated to depend upon their price (PF), the U.S. income level (YUS), the overall price level (CPI), and current and lagged imports (M):

$$QF_t^d = i(PF_t, YUS_t, CPI_t, M_t, M_{t-1}). \tag{6}$$

Own-price and consumer income are expected to enter the equation with negative and positive signs, respectively. Prices of all other commodities (CPI) should be negatively related to demand. In addition, the quantity of limes demanded depends as well on the availability of imported limes. Increased quantities of the imports should erode demand for the domestic product. The sustained increase in lime imports, evidence that foreign competitors are gaining market share, should negatively influence the demand for Florida limes.[1]

To complete the specification of the Florida lime market, we require that

$$QF_t^s = QF_t^d, \tag{7}$$

assuring a market-clearing equilibrium.

The Estimated Model

This economic model consists of four behavioral equations and three identities. The parameters of the behavioral equations were estimated simultaneously via three-stage least squares (3SLS) using annual observations for the period 1957 through 197[illegible]. The estimated equations are reported in table 1, along with their corresponding structural R_c^2's and the variable definitions.[2]

All four equations exhibit good structural fits, as evidenced by the high R_c^2's and the overall significance of the estimated parameters. Parameter signs conform to theoretical expectations. All variables enter the import supply equation with their expected signs at high levels of significance. In the import demand equation, the variable PM exhibits the expected sign but is only marginally significant. The income measure, YUS, also has the postulated sign but is not significant, perhaps due to its high degree of correlation with CPI. Finally, Florida lime production was the strongest explanatory variable in the import demand equation.

In the Florida supply equation, polynomial distributed lags were imposed on the price and cost series. Prices were assumed to follow a four-period, first-order, polynomial distributed lag, whereas production costs were allowed to follow a four-period, second-order distributed lag.[3] In both cases all parameters are of expected sign and highly significant, except for that on PPF_{t-1}. The large coefficient on QF_{t-1} reflects the substantial inertia which dominates the supply side of the Florida market. Finally, the Durbin m-statistic provides an appropriate test for residual autocorrelation because of the presence of a lagged dependent variable (Spencer).

The estimated Florida demand equation also conforms closely to the hypotheses. The price of Florida limes and domestic income influence the

---

[1] Ward and De found that lemons are not a significant competing crop with Florida limes. No attempt therefore was made to include lemon supplies in the Florida lime demand equation.

[2] The R_c^2 measure presented relates to a single structural equation before the third stage estimation takes place. It has been shown to be equivalent to the R^2 for a reduced-form equation when estimated by the partially restricted reduced-form estimation method (Knight).

[3] The calculated F-statistic for discriminating between the unconstrained lag model and the reported model was $F_{3,10} = .120$, indicating that the imposed lag forms do not contradict the sample data. A first-order polynomial distributed lag was investigated for the cost series, but a specification error test suggested by Harper rejects the polynomial degree at the .01 level.

Table 1. 3SLS Structural Equation Estimates of Model for Limes

Sources: Data were obtained from standard USDA, IMF, and other governmental publications.

Note: Endogenous variables: M_t is U.S. imports of limes at year t (m. lbs.); PX_t, Mexican lime export price (pesos/lb.); PM_t, U.S. lime import price ($/lb.); QF_t, Florida lime production (m. lbs.); PF_t, Florida wholesale lime price (¢/lb.). Exogenous variables: *YMEX* is real Mexican gross domestic product (deflated by Mexican wholesale price index; billion pesos); *YUS*, U.S. disposable personal income (billion dollars); *CPI*, U.S. consumer nondurable goods price index (1972 = 100); PPF_t, U.S. index of prices paid by farmers (1967 = 100); *FW*, Florida weather dummy variable (*FW* = 1 for years with unfavorable weather conditions, freezes or hurricanes; and *FW* = 0 in remaining years); *TIME*, annual trend term, 1957–58 season is year 1.

[a] This is the Carter-Nager measure of correlation as discussed by Knight for all equations except the Florida supply equation, where the OLS R^2 is reported.

[b] Asymptotic standard errors in parentheses.

[c] The hypothesis of no first-order autocorrelation of the OLS estimate of this equation could not be rejected at the .1 level using Durbin's alternative test as suggested by Spencer.

demand to a considerable extent. The estimated price and income elasticities of demand are −.0.64 and +2.00, respectively. In this equation, *CPI* has the proper sign but is not statistically significant, due perhaps to its high correlation with *YUS*. Current imports are only marginally significant. Lagged imports, however, appear to have a significant effect. This supports the hypothesis that sustained increases in imports have an adverse effect on the demand for Florida limes.

Model Validation

The reduced-form equations were derived and the endogenous variables were simulated over the sample period in order to evaluate the model's forecasting performance. Both static and dynamic simulations were performed using the estimated or base model. Unlike the static simulation which uses actual values for lagged endogenous variables, the dynamic simulation employs, instead, their previously solved values.

In order to assess the model's ability to track history, the squared correlations between actual and simulated values of the endogenous variables were calculated. The following results were obtained:

Simulation	Endogenous Variable				
	M	*PM*	*PX*	*FQ*	*PF*
Static	.94	.72	.93	.94	.96
Dynamic	.95	.76	.92	.89	.86

The reduced-form solution of the model under the two simulation strategies appears acceptable for all variables except the U.S. import price (*PM*). Because this variable has little impact on lime imports (*M*) in the structural model, imports are simulated quite accurately.

Trade Policy Simulations

Imports, Florida output, and Florida prices were simulated over the 1970–78 period under the current U.S. tariff policy (base value). Next, four alternative tariff and quota policies were incorporated into the model, and simulation results for the 1970–78 period were compared to the base solution values. The hypothetical trade policies considered are (*a*) a no tariff or free-trade policy, involving the elimination of the 1¢ per pound specific tariff on limes, (*b*) doubling of the current tariff to 2¢ per pound, (*c*) a further increase in the tariff to 5¢ per pound, and (*d*) the imposition of a fixed impor

Table 2. Simulated Values for Lime Imports, Florida Production, and Price under Alternative Trade Policies, 1970–78

Exogenous Variable	Trade Policy	Year 1970	1971	1972	1973	1974	1975	1976	1977	1978	Mean 1970–78	Change from Base Value (%)

	Import quota (M ≤ mill. lbs.)											

quota of 5 million pounds per year.[4] Table 2 shows the values of imports, Florida output, and prices over the simulation period.

The free-trade alternative implies an average increase in lime imports of 5.2% over the simulation period. Under the same policy, Florida production declines by an average of 2% per year, with no appreciable effect on Florida prices.

Doubling the existing specific tariff results in a moderate (2.2%) increase in Florida's output and a more substantial decline of yearly imports. Florida prices exhibit a negligible increase of .08% per year. The further increase of the tariff to 5¢ per pound results in a similar pattern. In this case, both the simulation of Florida's production and the discouragement of imports is more pronounced than under the previous alternative. Again, no appreciable effect is found on Florida prices, indicating a noninflationary impact for specific tariff increases on fresh limes.

Finally, imposing a fixed import quota of 5 million pounds per year implies a decline of over 50% in total imports during the 1977–78 period. This would have increased Florida output an average of 16.1% per year and Florida prices an average of 6.5% annually, suggesting a mean tariff equivalent of this quota of 9.8¢ per pound. This latter alternative is undoubtedly inflationary. Apparently, only increases in the U.S. specific tariff could benefit Florida growers without at the same time increasing the cost borne by U.S. consumers.

Conclusions

This estimated model shows that increased import competition, particulary from Mexico, had an adverse effect on Florida's market. Simulation of the model under alternatve U.S. trade policies yields some interesting results. The free-trade alternative would increase imports and reduce Florida's output without affecting Florida prices. Increases in the U.S. specific tariff level would decrease imports and stimulate production in Florida but would have only a limited upward impact on prices. Limiting imports to pre-1973 levels, via the imposition of a fixed import quota, would provide a considerable stimulus for increasing Florida's output and at the same time raise Florida prices.

These results clearly are positive rather than normative. U.S. trade policy for limes, as well as for other products, should not be established solely on the basis of benefits to specific producer groups, but on wider consideration of both producers and consumers.

[*Received August 1980; revision accepted March 1981.*]

[4] To examine the implications of a hypothetical fixed import quota the foreign trade sector was exogenized. The import quota of 5 million lbs./year was chosen to represent the approximate level of imports prior to the intensification of import competition in 1973.

Induced Innovations and Farm Mechanization

Yoav Kislev and Willis Peterson

There are two traditional explanations to the revolutionary machine-labor substitution in American agriculture. One is that technical change in agriculture caused machines to be introduced and labor to become unwanted. The alternative explanation is that, from the farm sector point of view, labor's exit is primarily a market phenomenon guided by rising urban opportunities and declining real machinery costs.

If mechanization and labor exit are due to technical change in agriculture, then they come mainly from the public agent of farm technology—the agricultural research system; the research system should be held responsible for the social consequences of farm mechanization, and it should be budgeted and directed accordingly. On the other hand, if mechanization and exit from farming are caused mostly by external price and wage changes, the responsibility of the research system is limited principally to technology improvement.

In this note we discuss the newly emerging tradition of induced innovation and its relation to the alternative explanations of machine-labor substitution in agriculture. We first clarify the conceptual basis of the induced innovation hypothesis and the related innovation possibility function. Second, we call into question the validity of some of the empirical applications. We argue that an incomplete conceptualization of the induced innovation idea has led to invalid empirical tests and to inappropriate implications on the causes of American farm mechanization.

The Hicksian Framework

It is useful to view the process of price-induced technical change as if it occurs in two stages. In figure 1 the initial isoproduct curve, I_1, and price ratio, P_1, result in an equilibrium, cost-minimizing combination of capital and labor at point A. As prices change to P_2, the new equilibrium point along I_1 is B. According to the induced innovation hypothesis, this change in relative prices causes an asymmetric shift in the production function. This is represented in the diagram by the shift in the isoquant from I_1 to I_2. Now the equilibrium point is at C for the price ratio P_2. The capital-labor ratio is increased in two stages: from A to B in response to the price change and from B to C in response to induced technical change.

Technological change is a function of the available stock of knowledge and the resources devoted to research and development. The concept of the innovation possibility function (the meta-production function in the terminology of Hayami and Ruttan) was introduced to formalize these relations. Hicks originally assumed innovation possibilities to be basically neutral; subsequent literature relaxed this assumption (Kennedy). If it is comparatively easier to develop technology that will save relatively more of a single factor, labor for example, one could say that the innovation possibility function is biased in a labor-saving or capital-using direction.

Biasedness need not be associated with price changes. In terms of the diagram, if technological changes took place and the innovation possibility function is biased in a labor-saving direction, then I_1 could shift to I_2 and equilibrium; still with the price ratio P_1, will move from A to D, increasing the capital-labor ratio.

Agriculture and Manufacturing

Much of the new technology that has affected productivity in agriculture was developed in the manufacturing sector and introduced into the farm sector, embodied in new or improved inputs—mechanical and chemical. The aggregate, economywide framework of the induced innovation hypothesis does not account for the intersectoral transfer of technology because the whole economy is taken as one sector. However, when applying the induced innovation idea to a single sector such as agriculture, it may be necessary to separate the sector where the technology is developed from the sector where it is used. Otherwise market phenomena reflecting farmers' responses to relative factor price changes may be mistakenly identified as technical change internal to agriculture.

Commonly, the output of certain manufacturing industries, such as machinery, commercial fertilizer, and other farm supplies, are counted as inputs to the farm sector in productivity studies. Alternatively, however, manufacturing and agriculture could be combined into a single sector. If combined, factors purchased by farmers from the farm

The authors are, respectively, senior lecturer in economics, Hebrew University, Rehovot, Israel, and professor, Department of Agricultural and Applied Economics, University of Minnesota.

Hans Binswanger, Yujiro Hayami, Terry Roe, and Vernon Ruttan read an earlier draft of the note; their comments were very helpful. The responsibility for the opinions expressed in the note and for its shortcomings are, however, the authors'.

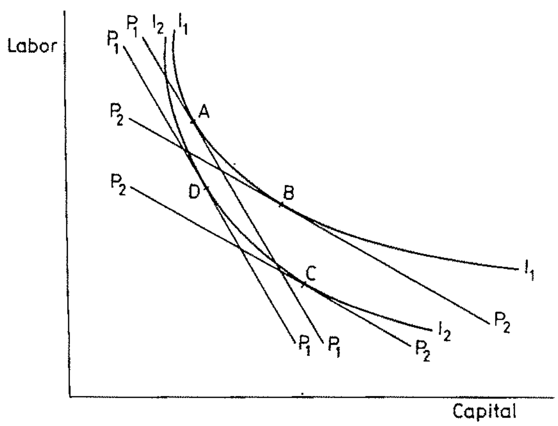

Figure 1. Induced technical change

supply industries will be regarded as intermediate goods, and the extrasectoral inputs will be such things as energy, steel, and raw materials, plus total capital and labor in the combined sector. In fact, the induced innovation hypothesis for agriculture originally was formulated (though not estimated) in the framework of a combined agriculture-manufacturing sector; at least this is how we read the theoretical sections of chapters 4 and 5 of Hayami and Ruttan.

In other cases, particularly if the empirical analysis is limited to agriculture, it is necessary to recognize explicitly that farming and manufacturing are two separate sectors. The induced innovation hypothesis as applied to agriculture should then be interpreted as the assertion that relative price changes induce innovations through two separate channels—external and internal. Innovations in manufacturing represent external technical change to agriculture which may or may not show up in the conventional estimates as productivity gains in the latter sector. If the new technology takes the form of product innovations, and if measures of the new or improved inputs (machines, let us say) do not accurately reflect quality changes, there may be a shift in the estimated agricultural production function as in figure 1. If it is a process innovation, such as the ability to produce nitrogen fertilizer at a lower cost, it may show up as a change in relative prices represented by a movement along an isoquant or production function. Better products often carry higher price tags, but farmers will not purchase the new or improved inputs unless their quality-adjusted prices are lower than the old input prices. Product innovations create, therefore, an identification problem. If these inputs are not adjusted for quality, farmers will be seen as increasing demand—buying more at higher prices. On the other hand, if these inputs are adjusted for quality, farmers will be seen as reacting to shifts in the supply of machine services—buying more at lower prices. In the latter case, there will be no measured technical change in agriculture; all of it will be seen to occur in manufacturing.

It is inconsistent to leave new or improved inputs created by product innovations in manufacturing unadjusted for quality, calling this technical change in agriculture, while treating process innovations which result in lower-priced inputs as a market phenomenon. As far as agriculture is concerned, both types of innovations are the same. Both result in lower effective prices of purchased inputs to farmers. Purchased inputs should therefore be adjusted for quality.[1]

Technical change also may occur in the agricultural sector, particularly if one defines this sector as including the research and development arm of farmers, namely, agricultural experiment stations. One might refer to the production of new varieties of crops, improved breeds of livestock, or new knowledge utilized directly by farmers as internal technical change, Machine-biased internal technical change might occur, for example, if new varieties of crops are adopted which require more mechanical services to insure proper timing of planting or harvest. In this case, farmers actually will increase their demand for machines and buy more of them even at higher real prices. Here, as elsewhere, one would not find productivity growth in agriculture if agricultural inputs were perfectly adjusted for quality. However, there would still be an increase in demand for machinery.

Empirical Application

Hayami and Ruttan did not explicitly separate internal and external technical change in their application of the concept of the induced innovation to agriculture. They were interested in international comparisons, particularly in demonstrating how agriculture of the comparatively capital-rich countries moved in the direction of labor-saving technology and how other countries, such as Japan, constrained by low land-labor ratios, developed and adopted land-augmenting innovations. For this analysis, the single-sector framework was a useful conceptualization and it was not crucial to distinguish between innovations in agriculture and innovations created in manufacturing. (Hayami and Ruttan did, however, discuss at length the mechanism of the transmission of the economic signals from commercial agriculture to the public agricultural research system.)

A detailed application of the induced innovation hypothesis to U.S. agriculture has been carried out by Binswanger for the 1912–68 period. His approach involved a two-stage estimation of the

[1] Quality unadjusted inputs are not only inconsistent in the analysis of technical change; they are simply meaningless. Inputs always should be measured in standard efficiency units. A simple addition of different quality tractors, for example, is as meaningless as adding apples and oranges.

biasedness of technical change in agriculture. First, elasticities of substitution in a five-input model of the farm sector were estimated. The second stage was an attempt to separate substitution of factors along isoquants in response to price changes from substitution due to biased technical change—shifts of the isoquants.

The real price of machinery in Binswanger's study is reported in table 1 (our data are discussed below). In his multifactor analysis, Binswanger employed the ratio of the price of machinery to the aggregate price of all inputs in agriculture. To focus on the machine-labor relation, we calculated from his data the implied ratio of machine price to the wage rate. In general, both ratios exhibit similar trends. The real machine price was comparatively high in the decade of the 1930s, mainly because of the decline in farm wage rates. In both series the real price of machines was higher after World War II than in the 1920s. The series differ in one respect: relative to all inputs, machinery prices are reported to increase substantially after the war; while relative to labor, machinery prices are comparatively stable for this period.

Whether the original five-factor perspective is adopted or the narrower two-input, labor and machinery point-of-view is taken, the data presented in part A of table 1 indicate that machine-labor substitution after World War II could not be a market phenomenon, i.e., it could not be a process of substitution in response to relative factor price changes. Indeed, Binswanger (p. 223) reports "that overall technical change was machinery-using, despite a substantial overall rise in the relative machinery price." These findings imply that internal farm sector technical changes which shifted the demand for machinery were the sole reason for the vast substitution of machinery for labor after World War II.

Table 1: Indices of Real Price of Machinery

	Ratio to			Ratio to	
Year	All inputs	Labor	Year	All inputs	Labor
A. Binswanger

B. Custom rates					
1930	100				
1950	56				
1970	35				

Sources: Binswanger, table 7-1; custom rates, Kislev and Peterson, table 3.
Note: Binswanger's data are ratios of machine prices to prices of "all inputs" or "labor." Custom rates are ratios of rates in combine harvesting to agricultural wage rates.

Internal technical changes could have occurred because of learning by doing or the introduction of new crop varieties and other inputs. However, from what we know about U.S. agriculture, it is hard to believe that farm mechanization after World War II should all be attributed to new varieties and similar on-the-farm factors. The development of the machine-adapted tomato varieties, for example, began in 1943, when the shortage of labor was strongly felt (Rasmussen). It is hard to think of other major clear-cut cases. Some of the new chemicals require new machines to apply but at the same time save on machines by reducing tillage work.

The main empirical difficulty we see with Binswanger's analysis is his failure to adjust machinery prices for quality changes. The official U.S. Department of Agriculture (USDA) machinery price index, which he used, has been shown to overstate the increase in machinery prices because quality changes are not accounted for (Griliches, Fettig). The USDA series also overlooks the substantial decrease in the effective cost of mechanical services caused by the increasing importance of income taxes, particularly the accelerated depreciation and investment credit provisions of the tax law. In an attempt to avoid these misspecifications, we collected data on custom rates in combine harvesting. These rates reflect the market evaluation of quality changes and other factors affecting cost of machines service.

The new custom-rate, wage-rate ratio reported in table 1 reveals a large decline in the relative cost of machinery. With these data, the explanation for farm mechanization becomes straightforward. Farmers demanded new and larger machines because the cost of farm labor, both the opportunity cost of family labor and wage of hired labor, increased relative to the prices of machinery services. Machinery manufacturers responded to this increase in demand by expanding capacity through investment in both research and development and plant and equipment. Thus, as we read the evidence, the technical change that encouraged farm mechanization occurred mostly in the manufacturing sector. Had the induced innovation hypothesis been more carefully formulated in terms of the interrelation between agriculture and manufacturing,[2] we believe that empirical work would have distinguished between internal and external technical change in turn leading to careful quality adjustment of machine price data and in the final analysis would have produced very different findings and policy implications.

[*Received October 1980; revision accepted March 1981.*]

[2] Although Hayami and Ruttan did not distinguish between internal and external technical change, they did adjust for input quality change in their attempt to explain changes in factor proportions in the United States and Japan by changes in factor price ratios (chap. 6).

The Economic Efficiency of Farmers Growing High-Yielding, Irrigated Rice in India

K. Kalirajan

The high-yielding varieties program has been operating for some fifteen years in India. As a result, the "modern" technology is no longer a "new" technology, particularly for irrigated rice farmers. The issue addressed in this paper, therefore, is whether farmers producing high-yielding varieties (HYV) of rice are doing so in an economically efficient manner, or do substantial opportunities remain to increase the efficiency of the farmers' application of modern rice technology? To get an empirical answer and to assess better the economic performance of farmers, a study area was chosen to approach ideal field conditions for implementation of the program. Economic performance can be measured by comparing the economic efficiencies of farmer groups (small and large). The profit function developed by Yotopoulos and Lau is used as an analytical tool to examine economic efficiency, including technical and price efficiency.

For the empirical estimation of profit and variable factor demand functions, a random sample of seventy farmers growing a HYV IR20 in rabi (winter) season 1977/78 was selected from a progressive village in the Coimbatore district, Tamil Nadu, a favorably placed area in terms of irrigation, administration, paddy varieties, and other such factors. The total population of the village, Seyyampalayam, consisted of about 55% of farmers having operational holdings of 1 hectare or less with an average of 0.64 hectare; the other 45% had operational holdings of above 1 hectare with an average of 2.79 hectares. Accordingly, equal representation was given to both groups (35 farmers each) in our random sample, defining a larger farmer as one with more than 1 hectare.

Input Availability and Use

The HYV program was introduced to Coimbatore in 1966. Since then there has been a rapid growth of both HYV adoptors and area. IR20 was introduced in 1969/70 and by 1972/73, it was grown almost exclusively in both seasons in the study area, Seyyampalayam. From 1975/76, two recently released location-specific, high-yielding varieties, ADT31 and CO37, gained popularity, replacing IR20 in the kharif season. In rabi season, however, IR20 retained its popularity. Almost 91% of farmers in the study area were growing IR20 during the survey period.

There was almost no input supply shortage reported during this survey. Nor were there any significant differences between large and small farmers in levels of application of inputs in the study area (table 1). All the participants were well served by canal irrigation, and the quantity and timing of water were adequate. Table 1 implies that there were no major constraints in the study area on input availability and use. This supports the findings of Barker and Herdt that small farmers have the same economic motivation as large farmers in adopting HYVs.

Empirical Profit and Factor Demand Functions

Assuming a Cobb-Douglas production function, the estimating equations of profit functions are

$$\ln\Pi = \lambda + \alpha^*_0 D_1 + \beta^*_1 \ln W + \beta^*_2 \ln F + \beta^*_3 \ln P + \beta^*_4 \ln B + \alpha^*_1 \ln A + \alpha^*_2 \ln C,$$

where Π is unit output price (UOP) profit in rupees; W is normalized rate for labor (man days), calculated by dividing the total wage paid to labor by the total number of laborers used all divided by the unit price of paddy; F is normalized fertilizer price, obtained by dividing the total expenditure on fertilizers by the total amount of fertilizer in kilograms and normalizing the ratio by UOP; P is normalized pesticides price, calculated by dividing the total amount spent on pesticides by total amount of pesticides in kilograms, and normalizing this ratio by UOP; B is normalized wage for a bullock pair per day, obtained by dividing the total expenditure on bullocks by the total pairs of bullocks and dividing this ratio by UOP; A is cultivated area in acres; C is capital flow, calculated as the sum of depreciation, maintenance, and opportunity costs of capital stock;[1] $D_1 = 1$ for small farm group, 0 otherwise;

The author is an economist, Department of Agricultural Economics, International Rice Research Institute, the Philippines. The analysis was done while the author was with the Department of Economics, Research School of Pacific studies, Australian National University.

The author is grateful to R. T. Shand and R. M. Sundrum, Department of Economics, Research School of Pacific Studies, Australian National University, and to referees of this Journal for their valuable comments and suggestions on the earlier draft.

[1] Depreciation is calculated by the straight line method, and opportunity costs are derived by multiplying the stock by 12%, which was the lending rate of the local cooperative societies.

Table 1. Average Input Applications to IR20 by Farm Size Group, in Rabi Season, 1977/78, and Other Farm Characteristics

	Average Application per Acre		
Inputs/Farm Characteristics	Large Farmers	Small Farmers	T-value
Hired labor (man-days)	187.52	189.14	0.36
Expenditure on pesticides application (Rs.)	98.54	100.34	0.47
Expenditure on other inputs (Rs.)	242.01	217.73	1.10
Nitrogenous fertilizer (kgs.)	41.89	41.63	0.18

and λ is constant. The variable factor demand functions are

$$\frac{-Wx_1}{\Pi} = \beta^*{}_1{}^S D_1 + \beta^*{}_1{}^L D_2,$$

$$\frac{-Fx_2}{\Pi} = \beta^*{}_2{}^S D_1 + \beta^*{}_2{}^L D_2,$$

$$\frac{-Px_3}{\Pi} = \beta^*{}_3{}^S D_1 + \beta^*{}_3{}^L D_2,$$

$$\frac{-Bx_4}{\Pi} = \beta^*{}_4{}^S D_1 + \beta^*{}_4{}^L D_2,$$

where x_1 is total labor man-days used; x_2, total chemical fertilizer used (kgs.); x_3, total pesticides used (kgs.); x_4, total bullock pair days; S, small farmer group; L, large farmer group; $D_1 = 1$ for small-farm group and zero otherwise; and $D_2 = 1 - D_1$.

Tests for Relative Efficiency

The first hypothesis to be tested is that there is equal relative economic efficiency among the small and large-farm groups in the study area. This requires that the UOP profit functions of small- and large-farm groups and their variable factor demand functions coincide with each other. These enable us to test for the two components of economic efficiency, (*a*) technical efficiency, whereby the greatest output is obtained from any given set of inputs in a technical production function, and (*b*) price efficiency, which involves equality between marginal value products and opportunity costs.

Testing equal relative economic efficiency empirically between small- and large-farm groups involves examining whether parameters of the UOP profit function of small- and large-farms are the same. This is equivalent to testing whether the dummy variable coefficient, $\alpha^*{}_0$, is zero.

The test for equal relative price efficiency between small- and large-farm groups is to examine whether both groups of farmers equate marginal value product to marginal cost of the variable factors to the same degree. This is equivalent to testing whether or not the elasticities of variable inputs of small ($\beta^*{}_i{}^S$) and large ($\beta^*{}_i{}^L$) farms, estimated from factor demand functions, are the same. The null hypothesis can be represented by the following equality:

(1) $$\beta^*{}_i{}^L = \beta^*{}_i{}^S,$$

where i is variable inputs: labor (1), fertilizer (2), pesticides (3), and bullock pair days (4).

A test for equal relative technical efficiency consists of testing the joint hypothesis of equal relative economic and price efficiencies, which is equivalent to testing the following equalities simultaneously:

(2) $$\alpha^*{}_0 = 0 \text{ and } \beta^*{}_i{}^S = \beta^*{}_i{}^L,$$

where $i = 1, 2, 3, 4$.

The next hypothesis to test is whether the farms (small or large) maximize their profits fully, equating marginal value products of the variable factors to market prices specific to these farmers. This is equivalent to testing whether the elasticities of variables factors ($\beta^*{}_i{}^S$ and $\beta^*{}_i{}^L$) estimated from the factor demand functions are equal to the respective elasticities estimated from profit functions ($\beta^*{}_i$); the appropriate null hypothesis is

(3) $$\beta^*{}_i{}^S = \beta^*{}_i \qquad \beta^*{}_i{}^L = \beta^*{}_i$$

where $i = 1, 2, 3, 4$. The above hypothesis concerns the absolute price efficiency of farms.

All hypotheses were tested by incorporating the respective equalities (1) and (3) as restrictions I ($\beta^*{}_i{}^L = \beta^*{}_i{}^S$), and II ($\beta^*{}_i{}^S = \beta^*{}_i$) and ($\beta^*{}_i{}^L = \beta^*{}_i$) in the estimation process. Aitken's generalized least-squares method (ALS) through a Lagrangian multiplier was used so that the estimated coefficients exactly satisfy the conditions imposed by the null hypotheses (Byron). After testing restrictions I and II separately, restriction III ($\beta^*{}_i{}^S = \beta^*{}_i$ and $\beta^*{}_i{}^L =$

$\beta^{*}{}_{i}^{S}$), which involves I and II taken together, was introduced in the estimation process to obtain profit and variable factor demand functions for further analysis. This way of estimating profit and factor demand functions is different from the Yotopoulos and Lau method. The advantage of working with this method is that it is possible to identify which elasticities estimated from the factor demand func-

tions differ from those of the profit functions. It helps policy makers to identify which of the factors are affecting farmers' decision making.

Results

Table 2 shows that since the coefficient (α^*_0) was not statistically different from zero at the 90% level, there was equal relative economic efficiency in the cultivation of IR20 in rabi season among small- and large-farm groups.

The results of the statistical tests of equal relative price and technical efficiencies are given in terms of λ and χ^2. The analysis showed that the null hypothesis of equal relative price efficiency of small and large farmer groups could not be rejected at the 10% level. The estimates of λ did not significantly differ from zero and the value of χ^2 was not significant. This indicates that the restrictions were satisfied and that there were no differences between price efficiency parameters of small- and large-farm groups. Similarly, the null hypothesis of equal relative technical efficiency between small and large farmer groups could not be rejected.

Because different farmer groups face different input and output prices and have different levels of fixed resources, the input combination that results in perfect (full) maximization will be farmer group-specific. Thus, the necessary and sufficient condition for full maximization is that each group should equate its marginal product of variable inputs to its specific market prices (Yotopoulos and Lau). The results of tests of full profit maximization of the small farmer group and also of the large farmer group showed that the null hypothesis could be rejected. The χ^2 was significant at the 5% level. This implies that both groups did not perfectly maximize their profits in utilization of the variable factors. Both groups were not using variable factors at optimum levels.

With the present method of estimation, it is possible to find out which of the factors were not used as optimum levels and why. Assuming that all restrictions were valid, it was found that the estimate of λ with respect to pesticides, estimated from the factor demand function and profit function, was significant at the 5% level in both cases. The significance of λ in relation to pesticides means that both farmer groups were not able to equate marginal value product and marginal cost for this factor.

This can be explained by the biological characteristics of IR20. It has been shown statistically that the sample farmers were unable to control completely the pest Brown planthopper (BPH), though they applied the recommended doses of pesticides. The main reason is that the maturity period of IR20 (130–35 days) does not enable the pesticides to work effectively on BPH. It coincides with the building up of BPH in the sample village. As a result, the marginal value product of pesticides fell below its marginal cost.[2] Thus, the local pest (BPH) was a disturbing factor affecting the sample farmers' decision making. Except for this constraint, all participants in general were more inclined toward the economic motivation of price taking and maximizing profit. This result conforms with that of Yotopoulos, Lau, and Lin in relation to the agricultural households in Taiwan.

Conclusions

Sample participants can be called economically efficient. This strongly disagrees with the pessimistic view of Hanumantha Rao that HYVs offered greater opportunity to bigger farmers, but it supports the findings of Rajagopalan that small farms have not lagged behind in growing and deriving benefits from HYVs. Parthasarathy and Prasad, with data from the rice-growing areas of Andhra Pradesh in India, also arrived at almost the same conclusion, that the relationship between size and productivity found in the pre-technology period is not apparent. With the exception of BPH control, this study shows that economic opportunities provided by the HYV program were utilized efficiently by sample participants regardless of farm size. Further, they all had the same economic motivation of maximizing profits.

Given the same access to inputs and equal terms, small farmers will respond to economic opportunities in the same way as large farmers. However, in order to achieve this, special institutional arrangements may be necessary to ensure equal access for small farmers to inputs.

The Inverse Relationship between Size of Land Holdings and Agricultural Productivity

Vaman Rao and Tosporn Chotigeat

The important relationship between the size of land holdings and agricultural productivity in developing countries has been debated intensely. From early Soviet debates to the extensive literature generated by the release of Farm Management Survey (FMS) data in India, the question of returns to scale and input productivities (primarily for land) in traditional agriculture has been confused and clouded by strong positions and ideological predilections.

Bhagawati and Chakravarty, Saini (1969), and Bharadwaj provide extensive bibliographies on the theoretical and empirical aspects of this problem in the Indian context. Briefly, Sen (1964, 1966), Mazumdar (1963, 1965), C.H.H. Rao (1966, 1970), Khusro, Saini (1971), Bhattacharya and Saini, more or less endorse an inverse relationship between the land size and its productivity. A. P. Rao (1963) and Rudra and Bandhopadhyay do not believe in the existence of an inverse relationship and argue that no systematic relationship can be established between any two variables describing land size and productivity. Bharadwaj and others dismiss the statistical validity of an inverse relationship, but generally accept it as a "stylized fact."

The approach used in these statistical studies is to employ aggregate, average or farm level data within a village or among different villages for all crops or a few specific ones. Various concepts of productivity and input variables are used. The actual regressions use linear or log-linear functional forms.

Using the pooled FMS data for several states in South India, this paper makes an attempt to reexamine, in a more general way, the relationship between the size of land holdings and agricultural productivity. This study employs the transcendental logarithmic (translog) function to formalize the relation between output and an arbitrary number of inputs. The translog function is not locally constrained by assumptions of homogeneity or additivity. Estimates of output elasticity with respect to land size for various values of cooperating inputs will indicate whether the alleged inverse relationship holds in any or all circumstances.

The Model

The transcendental logarithmic function was chosen as the basic functional form of the model. The properties of the translog function are discussed in Christensen, Jorgenson, and Lau, and Berndt and Christensen. The function is represented by (Model 1),

$$(1)\quad \ln y = \ln \alpha_0 + \sum_{i=1}^{N} \alpha_i \ln x_i + \tfrac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N} \beta_{ij} \ln x_i \ln x_j + E_i,$$

where y is output, the x_i are inputs, the Greek letters are parameters and $\beta_{ij} = \beta_{ji}$.

In this model the output elasticity with respect to x_{1i} is given by

$$(2)\qquad \eta_i = \frac{\partial \ln y}{\partial \ln x_i} = \alpha_i + \sum_{j=1}^{n} \beta_{ij} \ln x_j,$$

which can be evaluated at given values of x_j, the cooperating inputs. The signed measure of η_i, at different values of x_j, indicates the nature and magnitude of the relationship between the output and a selected input.

The estimation of parameters when using pooled data poses problems of serial correlation and heteroskadasticity. Because the FMS data used in this study are for different regions, different sizes of land holdings, and different time periods, it is reasonable to assume that cross-sectional units are mutually correlated and that there is serial correlation through time. Therefore, generalized least-squares regression was used (Kmenta, p. 512–14). After the initial estimation, if a particular variable was found to be not significant at $\alpha = .05$, it was dropped and the model was reestimated.[1] The choice of the particular set of regressors was based upon intuitive considerations and data availability.

Vaman Rao is an associate professor of economics at Western Illinois University, and Tosporn Chotigeat is an assistant professor of economics at Catholic University of Puerto Rico.

The authors are grateful to Stanley R. Johnson, Vernon Ruttan, Romesh Diwan, and an anonymous referee for valuable comments on an earlier draft of this paper. A version of this paper was presented by the senior author to the Chicago meeting of the Association of Indian Economic Studies (Allied Social Sciences Association).

[1] With this method, R^2 values could not be calculated to determine the goodness of fit. The R^2 calculated by using the sums of squares of regression and error of all the seven time-series combined did indicate that the translog model was a better fit compared to two simple models. The variables were tested for multicollinearity. No serious problems were encountered.

For the purpose of comparison with earlier studies, the following two single-variable and three-variable log-linear models were also estimated: (Models 2 and 3)

(3) $\ln y = \ln a + b_1 \ln x_1 + e,$ and

(4) $\ln y = \ln A = \Sigma B_i \ln x_i + v.$

The Data

For this study, FMS data for Alleppey and Quilon (Kerala) for the years 1962–63/1964–65, for Tanjavur (Tamil Nadu) for the years 1967–68/1969–70 (averages for three years) and for Cuddapah (Andhra Pradesh) for 1967–68/1969–70 were used. Even though the cropping patterns in the three areas are not the same in all details, the main crops (rice and millets), cultivation practices (fertilizers and varieties of seeds), and institutional features (landlord-tenant relations and credit availability, etc.) are not dissimilar. Pooling of data was necessary to obtain a sufficient number of observations.

Six dependent variables were defined which directly or indirectly represent the productivity of land: Y_1 is the gross value of output per cultivated hectare, and Y_2 is the same measure per cropped hectare; Y_3 and Y_4 are farm business income per cultivated and cropped hectare, respectively; Y_5 and Y_6 are net farm business income, respectively, per hectare of cultivated and cropped land. Obviously, Y_1 and Y_2 are measures of physical productivity; Y_3 and Y_4, on the other hand, are measures of profitability obtained by deducting all production costs actually incurred from gross output values. They motivate all farming operations, including decisions such as choice of production techniques. If the rent paid to the landlord for leased-in land also is deducted, then the net farm business income variables, Y_5 and Y_6, are obtained. The last pair is important in considering the effect of land ownership on productivity. All values are expressed in current market prices. Regional disparities in prices are negligible, and year-to-year changes in output prices are not likely to distort the results because they affect all sizes equally. A word about the distinction between the cultivated and cropped areas is necessary, because it has generated controversy in earlier literature. The cultivated area represents the total arable area of land held, including current fallow (usually less than 1%). Multiple cropping generally increases the cropping intensity to more than 1.0. The cropped area, therefore, represents the equivalent of the land used for single cropping. One measure represents the actual size of the holding and the other, the effective size.

Nine regressors have been defined: X_1 and X_2 are two measures of land, X_1 being the average size of the holding and X_2, the average size of a fragment Both are measured in hectares. X_1 represents the average area of an enterprise and possibly could be composed of several noncontiguous fragments. The noncontiguity may make it difficult for the farmer to adopt a production technique appropriate to the size of the holding. X_1, therefore, is not a true indicator reflecting the choice of production technique. Hence, X_2 is a second measure of the land size variable. Labor is measured as man-days; X_3 is total family labor, and X_4 is the total hired labor used per hectare. X_6 represents the current costs on capital equipment, including costs incurred on implements, fertilizers, seeds, irrigation, etc. These costs have been further classified in two ways: X_7 includes capital costs used in traditional methods of farming, and X_8 are costs on capital inputs generally incurred in nontraditional modes of agricultural production. This distinction was arbitrary and followed a common perception of what generally is believed to be traditional versus modern. A second way of classifying the capital costs was on a functional basis. Capital inputs that performed the functions of land were included in X_9, and those that displaced labor were included in X_{10}. Fertilizers and high-yielding variety seeds are the examples of the former, and improved ploughs and tractors are the examples of the latter. In effect, all the nine regressors represented different aspects of land, labor, and capital.

The Results

The estimated coefficients of model 2 (not reported) revealed that there is no systematic pattern of relationship between the land size and productivity. Average size of holding (X_1) was found to be significantly related only with net farm business income per cultivated hectare (Y_5). Similarly, average size of fragment (X_2) displayed a significant relationship with net farm business income (Y_5, Y_6). These relations were inverse, even though Khusro and Mazumdar (1963, 1965) argue that there is a positive relation between land size and farm business income. The only other significant relationship was between average size of fragment (X_2) and gross value of output per cultivated hectare (Y_1). This was also positive, rather than inverse. The coefficients of model 3 (not reported) had much the same story to tell.

The coefficients of the translog model, reported in tables 1 and 2, make it clear that the relationship is much more complex than is reflected by the simple models. It is also clear that there is not a systematic relationship between all the measures of productivity defined in this study and land size. However, in cases where the relationship can be systematically explained, the separate effect of land alone is not always significant. But land size does significantly explain variation in productivity in association with other inputs. Therefore, the negative signs associated with the coefficients of X_1 and X_2,

while important, should not be taken to reflect the total relationship between the land size and productivity. The signs of multiplicative terms are mathematically consistent with the signs of the individual terms.

The total relationship can best be explained by output or business income elasticities computed at given values of other inputs, table 3. For this paper, the maximum, the average, and the minimum values of cooperating inputs from the sample data are used. The sign of the elasticity measure depends on the signs of the estimated coefficients and the values of the cooperating inputs. An analysis of these signs will show the role of the cooperating inputs in the overall relationship.

The elasticity of Y_1 with respect to X_1 diminishes as the values of cooperating inputs are increased, ultimately reaching a negative value. This means the gross value of output per cultivated hectare increases at a diminishing rate with average size of holding when more and more units of cooperating inputs are used. At maximum values of both cooperating inputs, larger average size of holdings generate lower gross value of output per cultivated hectare. The signs of the estimated coefficients suggest that capital (X_6) has a consistent positive effect and labor (X_3) and land (X_1) have consistent

Table 3. Output or Business Income Elasticities

	With Minimum Values of Cooperating Inputs	With Average Values of Cooperating Inputs	With Maximum Values of Cooperating Inputs
Y_1 wrt X_1	.3808	.0314	−.0719
Y_2 wrt X_1	.2829	−.2345	.2837
Y_3 wrt X_1	−.4097	.0399	.4263
Y_1 wrt X_2	.2843	.0383	.1490
Y_2 wrt X_2	.5023	1.1665	1.1892
Y_3 wrt X_2	−.1858	−.1250	.2467
Y_6 wrt X_2	.3527	−.0130	.1271

negative effects on the elasticity measure. The net effect, however, depends on the individual effects acting in conjunction with one another. Thus, large doses of capital and small doses of labor acting in opposition to one another will insure a positive relation between land size and productivity, as measured by gross value of output per cultivated hectare.

The elasticity of Y_2 with respect to X_1 first diminishes and then increases as both cooperating inputs are increased. This peculiar effect is the net result of positive effects of capital and negative effects of labor and land. As the doses of labor and capital are increased, the larger negative effect of land and labor dominates the smaller positive effect of capital. But with larger doses of capital, the dominance is gained by capital, finally resulting in a positive measure of elasticity. When farms are multiple cropped, large amounts of capital and labor ensure a positive size-productivity relation.

The elasticity of Y_3 with respect to X_1 is negative with minimum and average values of cooperating inputs, but it becomes positive at maximum values. This relationship confirms the positive relationship suggested by earlier studies between land size and profitability. The elasticity of several measures of productivity with respect to average size of fragment also can be explained similarly since they

follow the general pattern suggested by average holding size.

In summary, capital has a positive effect and land and labor negative effects on the elasticity of gross value of output per unit of land. However, large doses of capital can compensate for the negative effects and a positive total relation between land size and productivity can be obtained. This result is of considerable significance when analyzing the choice of techniques in India's agricultural sector. Large-sized farms with capital-intensive techniques can obtain higher productivity with increased land holdings, especially with multiple cropping.

A further analysis was carried out to examine the relative importance of different types of labor and capital. The computation of elasticities revealed that for farm business income, the larger the component of hired labor and the smaller the component of family labor, the larger is the elasticity with respect to land size. Similarly, the larger the component of nontraditional capital equipment, or the smaller the component of traditional capital equipment, the larger is the business income elasticity with respect to land. Larger sizes of labor-saving capital or smaller sizes of land-saving capital will also increase the measures of both output and business income elasticities with respect to land size.[2]

The results suggest that larger-sized land holdings are not less productive, in all circumstances, as may be generally believed. If hired labor is employed in preference to family labor and if more nontraditional capital as opposed to traditional capital is used, larger-sized holdings and higher productivity can go together.

A General Measure for Output-Variable Input Demand Elasticities

Barry C. Field and P. Geoffrey Allen

In recent years the development of new production function forms has given impetus to empirical work of measuring input demand and substitution elasticities in a variety of industries. The so-called "flexible" functional forms have given us a much richer set of tools to investigate these relationships, as compared to the familiar Cobb-Douglas and constant-elasticity-of-substitution functions. The majority of researchers have reported their results in terms of input parameters estimated under the assumption of fixed output. While this is appropriate for some questions, we argue in the next section that output-variable measures often will be more useful for the problem at hand. In the third section, we derive a general expression for the output variable price elasticity of input demand, of which the well-known expression of Allen is a special case. Last, we discuss this measure in the context of several specific functional forms.

The Question of Output Variability

Although a bewildering number and variety of input substitution and demand parameters have been put forth by researchers, perhaps the most widely used measure is the simple price elasticity of input demand:

$$\epsilon_{ij} = \frac{\partial \ln X_i}{\partial \ln P_j} \bigg| \; Q, P_k \text{ for all } k \neq j,$$

where X_i is the quantity demanded of the ith input, P_j the price of the jth input, and Q refers to total output. To be consistent with demand theory, this is the elasticity whose sign should determine whether an input pair are substitutes or complements. It also may be expressed in a slightly different form: $A_{ij} = \epsilon_{ij}/S_j$, where S_j is the share of the jth input in total cost. A_{ij} is the Allen-Uzawa partial elasticity of "substitution," so called despite the fact that it is simply a normalized price elasticity of demand.

The elasticity ϵ_{ij}, calculated under the assumption that output is held constant, can indicate the characteristics of particular production surfaces that influence policy direction, i.e., the matter of substitutability and complementarity among inputs. Combinations of ϵ_{ij} also can be used to construct higher-order elasticities of substitution to study the curvature properties of production surfaces.

For matters of public policy, however, the assumption of constant output is often a disadvantage. There we are usually concerned with measuring the consequence of particular actions; for example, the effects of given subsidies on capital, of limits on land inputs, or of increases in energy prices. To be complete, we must take into account both input substitutions along given isoquants and the effects of output changes on input demand. What are needed in this case are measures of total elasticity:

$$\eta_{ij} = \frac{\partial \ln X_i}{\partial \ln P_j} \bigg| \; P_k \text{ for all } k \neq j.$$

In this case, quantities of all inputs as well as output are allowed to adjust to input price changes.

The expression that results, equation (4) below, is similar to the Slutsky equation of consumer demand theory. Thus, the general measure is somewhat analogous to the difference between ordinary and compensated demand curves in consumer behavior. The ϵ_{ij} above are analogous to elasticities on the compensated demand curve; whereas, for predicting real-world changes in consumption, we wish to know the elasticities of the ordinary demand curves. For most goods it will not make much difference which measure is used because consumers normally will spread their incomes over a large number of goods. On the production side, however, this is not the case. Most production functions contain only three or four measured inputs. For many of these inputs, therefore, the difference between elasticities with and without an output effect could be considerable.

One output-variable input demand elasticity already is available. In the case of constant returns to scale (CRTS) in production but a downward sloping output demand function, changes in output are produced when the cost function shifts, the extent of the output change being related to the price elasticity of output demand. This total input demand elasticity was provided by Allen (p. 508). Output effects also can be produced, even with a constant output price, if the production function is non-

The authors are an associate professor and an assistant professor, respectively, in the Department of Food and Resource Economics, University of Massachusetts.

Massachusetts Agricultural Experiment Station Paper No. 2390.
The authors would like to thank two anonymous referees for comments on an earlier version.

CRTS. In this case, shifts in a sloping cost (supply) curve over a horizontal demand curve produce changes in output. Of course output effects could result from both a downsloping output demand function and non-CRTS in production. In the next section we derive a general expression for the output-variable elasticity of substitution.

A General Expression

To derive a general expression for η_{ij}, i.e., one that permits both nonconstant returns and nonconstant output price, we make use of the following relations: production function $Q = f(X)$, dual minimum cost function $C = C(P,Q)$, and demand function $Q = \phi(R)$, where X and P are n-tuples of input quantities and prices, respectively, Q is output, and R is output price. Market clearing requires that marginal cost equal output price, or

$$C_q(P,Q) = \phi^{-1}(Q). \tag{1}$$

We use subscripts to denote partial differentiation with respect to that variable. By differentiating (1) totally, setting $dP = 0$ for all but the jth factor price and rearranging, we get:

$$\frac{\partial Q}{\partial P_j} = \eta \quad \frac{C_{qj}Q}{(R - C_{qq}Q\eta)},$$

where $\eta = \partial \ln Q/\partial \ln R$, the price elasticity of demand for output.

According to Shepard's lemma, $\partial C/\partial P_i = C_i = X_i(P,Q)$, the cost-minimizing demand curve for input i. Differentiating this demand curve with respect to the jth factor price gives

$$\frac{\partial X_i}{\partial P_j} = C_{ij} + C_{iq}\frac{\partial Q}{\partial P_j}. \tag{3}$$

Using (2) and substituting appropriately gives[1]

$$\eta_{ij} = \left.\frac{\partial \ln X_i}{\partial \ln P_j}\right|_{P_k,\, k \neq j} = S_j(A_{ij} + \eta\psi) = \epsilon_{ij} + S_j\psi\eta,$$

where $S_j = P_jX_j/C$, the share of the jth input in total cost; $A_{ij} = CC_{ij}/C_iC_j$, the Allen-Uzawa elasticity of "substitution" expressed in terms of the cost function, and

$$\psi = \frac{C_{iq}C_{jq}Q^2}{C_iC_j(1 - R^{-1}C_{qq}Q\eta)}.$$

Suppose we have a downward sloping demand curve: $0 < |\eta| < \infty$, and CRTS. In this case, marginal cost is constant, or $C_{qq} = 0$, giving

$$\psi = \frac{C_{iq}C_{jq}Q^2}{C_iC_j} = 1$$

since CRTS implies $C_i = QC_{iq}\ \forall\ i$. This gives the expression derived by Allen (p. 508):

$$\eta_{ij} = S_j(A_{ij} + \eta). \tag{4}$$

There are two cases where the expression gives constant-output elasticities, either CRTS ($C_{qq} \to \infty$) or a perfectly vertical demand curve ($\eta = 0$).

The case that has not been considered before is that characterized by $\eta \to -\infty$ and $C_{qq} > 0$, where the output effect is produced by the shifting of a sloping supply curve over a horizontal demand curve. In this case,

$$\lim_{\eta \to -\infty} (\eta\psi) = -A_{ij}\frac{C_{iq}C_{jq}}{C_{ij}C_{qq}},$$

giving

$$\eta_{ij} = S_jA_{ij}\left(1 - \frac{C_{iq}C_{jq}}{C_{ij}C_{qq}}\right). \tag{5}$$

Special Cases

It is of interest to consider the case of an output-price-constant, quantity-variable elasticity, equation (5), in the case of specific production function forms. Several recent studies (Sidhu and Baanante; Yotopoulos, Lau and Lin) have used a non-CRTS Cobb-Douglas function: $\ln Q = \Sigma_i\alpha_i \ln X_i$, with, of course, $A_{ij} = 1$, and $\Sigma\alpha_i = \mu < 1$.[2] In this case, making appropriate substitutions into (5), and recognizing that $\alpha_j = S_j/\mu$,

$$\eta_{ij} = -\frac{\alpha_j}{1 - \mu},$$

a result that was derived originally by Lau and Yotopoulos. Note that, as long as decreasing returns to scale pertain (i.e., $\mu < 1$), all inputs will be judged "complements" ($\eta_{ij} < 0$) despite the fact that $A_{ij} = 1\ \forall\ i, j$. This is another manifestation of the Cobb-Douglas inflexibility.

In the case of a multiple-input CES function,

$$Q = (\Sigma_i\alpha_iX_i^{-\beta})^{-\frac{\mu}{\beta}},$$

with a cost function of

$$C = Q^{\frac{1}{\mu}}\left(\Sigma_i\alpha_i^{\frac{1}{1+\beta}}P_i^{\frac{\beta}{1+\beta}}\right)^{\frac{1+\beta}{\beta}},$$

we have

$$\eta_{ij} = S_j\sigma\left(1 - \frac{1}{\mu}\right),$$

[1] This step makes use of the zero-profit condition, $C = RQ$, and of the symmetry conditions, $C_{ij} = C_{ji}$ and $C_{qi} = C_{iq}$.

[2] The non-CRTS functions in these studies involved subsets of inputs from overall functions that are CRTS. Suppose, on the other hand, we have an overall function that is non-CRTS but has a subset of inputs that are CRTS (when all inputs not in the subset are held constant). Then the elasticities of equation (4) apply only to this subset of inputs and are constructed from shares, S_j, Allen partial elasticities, A_{ij}, and "output" elasticities that refer to this subset of inputs. Of course, to analyze an overall production function in which some inputs are fixed and some variable would require a different analysis than that presented above.

where $\sigma = \dfrac{\beta}{1+\beta}$. Finally, suppose we have a translog cost function:

$$\begin{aligned} \ln C = {} & \ln\alpha_0 + \Sigma_i\alpha_i \ln P_i + \alpha_q \ln Q \\ & + 1/2\Sigma_i\Sigma_j\gamma_{ij}\ln P_i \ln P_j + \\ & \Sigma_i\gamma_{iq}\ln Q \ln P_i + 1/2\gamma_{qq}(\ln Q)^2, \\ & i, j = 1, \ldots, n. \end{aligned}$$

In this case,

$$\eta_{ij} = S_j A_{ij}\left[1 - \frac{(\gamma_{iq} + S_i S_q)(\gamma_{jq} + S_j S_q)}{(\gamma_{ij} + S_i S_j)(\gamma_{qq} + S_q^2)}\right],$$

where

$$\begin{aligned} S_i &= \alpha_i + \Sigma_k\gamma_{ik}\ln P_k + \gamma_{iq}\ln Q, \text{ and} \\ S_q &= \alpha_q + \Sigma_k\gamma_{kq}\ln P_k + \gamma_{qq}\ln Q. \end{aligned}$$

If factors i and j are substitutes, then $(\gamma_{ij} + S_iS_j) > 0$. Furthermore, positive marginal cost, monotonicity, and decreasing returns to scale imply that $S_q > 0$, $S_i, S_j > 0$, and $\gamma_{qq} > 0$, respectively. Homotheticity requires that $\gamma_{iq} = 0 \;\forall\; i$. In this case, the output variable elasticity will be less than the output constant elasticity (i.e., $\eta_{ij} < S_jA_{ij}$). It need not be always negative, however, as is the case with the *CD* function. If the function is sufficiently nonhomothetic, the "output" effect could lead to $\eta_{ij} > S_jA_{ij}$. If total output decreases as the supply function shifts up (assuming decreasing returns to scale), nonhomotheticity of the right type and magnitude (say γ_{iq}, strongly negative while γ_{jq}, close to zero) could give larger output-variable elasticities than output-constant elasticities. In this case the "warping" of the isoquants is strong enough to offset the impact of the change in output.

Capital Asset Pricing and Farm Real Estate: Comment

Colin Carter

In a recent issue of this *Journal*, Barry employs the capital asset-pricing model (CAPM) to explain farm real estate returns in the context of a well-diversified market portfolio. He finds that a significant portion of returns to farmland are not explained by his model and they can therefore be classified as "nonmarket" returns. The two major claims of his paper are that it provides evidence that farm real estate has low risk relative to other assets and that the CAPM framework provides insights into the effects of nonfarm investor behavior. Empirical support is provided by Barry for the former and little or no discussion is offered by him in relation to the latter. The purpose of this comment is to suggest that farmland returns are not dictated by returns in a portfolio comprised of bonds, stocks, and farmland, and it is unsuitable to investigate them with the CAPM model which assumes they are.

In an equilibrium setting, the CAPM develops a measure of the risk of an asset and the consequent relationship between the asset's risk and its one-period expected return. The major result of the CAPM is often expressed as

$$E(R_j) - i = \beta_j[E(R_m) - i], \tag{1}$$

where $E(R_j)$ is expected return on asset j; i, return on a riskless asset; β_j, cov $(R_j, R_m)/\text{var}(R_m)$; and $E(R_m)$, expected return of the efficient portfolio.

Even though the characteristics of common stocks and investors in these stocks come reasonably close to satisfying the assumptions of the CAPM,[1] the model has been criticized heavily for its limited operational usefulness when used to explain returns on these financial assets. For example, Roll recently has questioned the validity of the CAPM because, he argues, it has never been empirically validated. This questions the application of such a model to a nonfinancial asset such as farmland, which is noted for its indivisibility and illiquidity. Simply stated, farmland comes a long way from satisfying the CAPM assumptions. Because farm real estate is not a financial asset in the traditional sense of the word, it is tenuous to argue that its equilibrium returns will adjust to a level that reflects the risk it contributes to an efficient market portfolio of all financial assets.

The market index in the CAPM is designed to reflect the wealth composition of the representative investor under consideration. Because Barry is investigating nonfarm investor behavior, the market index he constructed should not contain a significant amount of farm real estate. Augmenting his stock and bond index with a farm real estate price index is not a true representation of nonfarm wealth. Furthermore, some farm real estate is implicit in the Standard and Poor 500-stock index to begin with. It is not surprising that Barry estimates a national beta (β) value of .19 for farm real estate returns since his estimate was formed by regressing real estate returns on a wealth index which was explicitly designed by him with .18 real estate returns. That is, the estimated beta value is simply a reflection of the 18% weight he gave farmland in his index of wealth (the independent variable R_m). He undoubtedly would have increased the estimated beta value if he had increased the proportion of the market index represented by farm real estate and vice versa if he had decreased the proportion.

Table 1 reports annual percentage returns in the farmland market and the stock market for the years 1956–73. The farmland returns represent changes in land values only. Over the twenty-three-year period, farmland returns were always positive and averaged 8% per annum, with a coefficient of variation of 6%. On the other hand, returns in the stock market were much more irregular and much more volatile. They averaged 4% per annum, with a coefficient of variation of 27%. These aggregate data indicate that farmland is not a risky investment in relation to financial assets such as common stocks. The data question Barry's initial assumption that a risk premium is required to encourage investors to hold farmland.

Using the ordinary least squares technique, the farmland returns from table 1 were regressed on the common stock returns. The estimated beta value was −.1 and was found not to be statistically different from zero at the .05 level as the t-statistic was −1.2. Thus, farm real estate returns are independent of common stock returns (i.e., their beta value was approximately zero). The zero beta asset does not contribute to the diversification of the total stock portfolio, and hence its inclusion in a nonfarm investor's portfolio cannot be justified. Therefore,

---

Colin Carter is an assistant professor in the Department of Agricultural Economics and Farm Management, University of Manitoba, Canada.

[1] The critical assumptions of the CAPM are that any investor can borrow or lend as much as he or she desires at the risk-free rate, each investor is a risk-averse utility maximizer, and investors agree about the distribution of the end-of-period asset values.

even if farmland could be viewed as a financial asset, it would be a riskless asset.

The positive and statistically significant alpha values estimated by Barry imply that farm real estate has offered substantial return premiums above those dictated by the market. This result indicates that investment in farm real estate "outperformed" the market. Does this imply that farmland is severely underpriced or does it indicate the inappropriateness of the CAPM model, equation (1)? Barry does not address this question. The most plausible hypothesis seems to be the inappropriateness of the CAPM, for reasons given above.

Unlike industrial real estate, farmland has not been a risky investment for nonfarm investors. Barry has applied the CAPM to estimate risk premiums required to hold farm real estate in a well-diversified market portfolio. He has assumed implicitly that farmland is not only as liquid as any financial asset, but also that it is a risky asset.

This comment is concerned with the use of the CAPM for the purpose of valuing farm real estate and it points out that farm real estate adds nothing in the way of diversification to a standard market portfolio because farm real estate is virtually a riskless asset.

Capital Asset Pricing and Farm Real Estate: Reply

Peter J. Barry

The major purposes of Colin Carter's "Comment" on my article are "to suggest that farmland returns are not dictated by returns in a portfolio comprised of bonds, stocks, and farmland, and it is unsuitable to investigate them with the CAPM model which assumes they are." His discussion includes the following items: (*a*) effects of nonfarm investor behavior, (*b*) CAPM applicability to farmland, (*c*) composition of the market portfolio, and (*d*) a numerical illustration of the correlation between changes in values of farmland and common stock. My "Reply" responds to these four items and raises some concerns about several points in his paper.

Carter characterizes my study as ". . . investigating nonfarm investor behavior . . . " and claiming that the ". . . CAPM framework provides insights into the effects of nonfarm investor behavior." This interpretation is too strong. My study was not designed to evaluate the behavior of nonfarm investors. While concern with nonfarm investment in agriculture helped to motivate the study, the analytical approach simply used the CAPM to estimate risk premiums required to hold farm real estate in a well-diversified market portfolio. The empirical results indicated that investment in farmland is a favorable source of diversification for well-diversified investors, which may strengthen the nonfarm sources of demand for investment in farmland. I also suggested, in a general appraisal, that the CAPM's equilibrium framework for risk pricing may have rich implications for future analyses of investor behavior, market characteristics, and policy issues in agriculture.

The second item is Carter's concerns about the CAPM's limited applicability to a nonfinancial asset like farmland and about my alleged failure to evaluate this applicability. Indeed, in the relatively short space of my article, I developed as fully as possible the prevailing mixture of views on the CAPM's usefulness, and identified from CAPM theory several sources of bias in its application to farm real estate. In particular, I inferred from Levy's theoretical analysis that CAPM results for farm real estate may understate the true beta values and overstate the true alpha values. These biases arise from the CAPM's restrictive assumptions about characteristics of investors and markets for farm real estate. They include the combined effects of limited diversification, high transactions costs, tax obligations, indivisibilities, thin markets, and other liquidity characteristics of farm real estate. Hence, I did address these issues, and still concluded in a positive light that farm real estate has low risk relative to other investments, and that the CAPM framework may prove useful for other analyses in agriculture.

The third item is Carter's contention that the market portfolio should not include the asset (farm real estate) whose risk-return characteristics are being evaluated. As pointed out in my article and verified in the finance literature, a basic CAPM principle is that the market portfolio should contain values of all assets that contribute to wealth. Included would be corporate securities, other financial assets, personal assets such as real estate, assets held by unincorporated businesses, human capital, and so on. Because the true market portfolio and its rate of earnings are impossible to measure, CAPM applications use various indexes as market proxies. Most indexes are narrowly defined; an example is a stock market index like the Standard and Poor's 500.

However, analyses with more broadly defined market indexes are becoming common. Sharpe, for example, used a composite stock and bond index in a CAPM application to bond investments. So did Friend, Westerfield, and Granito. Hohlthausen and Hughes indicated the need to use a combined stock and commodities index, although the absence of appropriate weights for stock and commodities precluded its use. CAPM results for a more comprehensive market index are reported by Ibbotson and Fall. They formulated a "market wealth portfolio" based on annual values of common stock traded on the major stock exchanges and over-the-counter, corporate bonds, commercial paper, short-and long-term municipal bonds, four types of U.S. government securities, farm real estate, and residential housing. Their results at the national level over the 1947–78 period gave a beta value of .10 and an alpha value of 4.33 for total real estate, which conform closely to mine.

Thus, CAPM theory and empirical studies give strong support for using a broadly defined index for the market portfolio. From a technical standpoint, however, Carter is correct that including the asset being evaluated in the market portfolio should increase the beta value. In my study, regressions of excess returns to farm real estate on the stock index alone and on the stock and bond index yielded beta values of .08 and .12, respectively, which are below the beta of .19 for the combined index of stock, bonds, and farm real estate. However, it is not clear

Peter J. Barry is a professor of agricultural finance at the University of Illinois.

why Carter expresses an element of "surprise" about the beta of .19 from the combined index. The estimated level of beta signifies the magnitude of relationship between changes in excess rates of return on farm real estate and changes in excess returns on a market index that contained on average about 18% farm real estate over the study period. While a relatively low beta value was anticipated, there was no cause for nonsurprise along the lines suggested by Carter. What "surprise" would occur if the beta were 1.5, 2.0, or some other value?

The final item concerns Carter's numerical example, which appears to illustrate the degree of correlation between changes in values for aggregates of two assets: common stock and farmland. The degree of correlation is found not to differ from zero. There is no basis for attributing this relationship to a CAPM application. Rather, the zero correlation simply implies that these farmland returns are independent of common stock returns. As in any portfolio analysis, zero correlation between two assets means that an investor may gain stability by diversifying his holdings to include the two assets, although in this case farm real estate is more risk efficient than common stock. Carter's suggestion that farmland be regarded as a riskless asset in relation to common stock is interesting. The opposite suggestion could occur too: that common stock be regarded as a riskless asset in relation to farmland.

Carter's figures for coefficients of variation (CV) also appear incorrect. Based on the statistics in table 1 of his comment, the CV values are .625 for farm real estate and 2.75 for common stock. Finally, the reference to differences in risk between investments in industrial real estate and farmland is unverified.

In conclusion, I appreciate Carter's comments and hope that my replies shed further light on risk pricing of farm assets relative to other assets. Moreover, to reiterate earlier comments, I believe that the CAPM offers a broad and rich framework for considering the effects of investor behavior, market characteristics, and public policies on risk pricing.

Books Reviewed

Burns, Joseph M. *A Treatise on Markets: Spot, Futures and Options.* **Washington, D.C.: American Enterprise Institute for Public Policy Research, 1979, 145 pp., $5.25 paper.**

This work is heralded as extending the ideas of Marshall on spot markets and those of Keynes and Hicks on futures markets, and adding a theory of option markets. The central theme is that futures markets typically develop in response to economic forces in spot markets. In turn, futures markets facilitate the work of spot markets. Option markets typically develop in response to forces in spot and/or futures markets and, in turn, help spot and futures markets work better.

In a chapter on "Spot Markets" Burns argues that market efficiency means improved "market liquidity," more "orderliness of market conditions" and better "quality of market organization." Liquidity (the most important of the three) is a function of (*a*) the certainty of the expected value of the asset and (*b*) its expected marketability. (It would have been helpful here if the author had considered Hicks' 1962 article on "Liquidity," containing this formulation). Disorderly markets are those whose prices are monopolized or are made artificial by false rumor or by overreaction of traders. Improved quality of market organization results from more specialization and economies of scale in the conduct of exchange. While liquidity begets orderliness of markets and improves market organization, the influences also run from each of the latter to improved liquidity.

Continuing Burns' discourse, the greater the number of kinds of related markets, the larger are likely to be the induced effects of more efficient markets. Thus, market development in an advanced economy may have immense economic benefits. In particular, futures markets make for more efficient spot and forward markets, encouraging their decentralization and, therefore, more accurately reflect local supply and demand conditions. Local prices, which may seem erratic, actually become more flexible and competitive. The new futures trading in financial instruments and foreign currency likely will yield the most pronounced benefits because their underlying spot markets touch all economic activity.

Futures markets, analyzed in the next chapter, contribute uniquely to market efficiency. Observable prices convey information about unobservable prices. The better futures estimate later spot prices, the better the information. Burns then elaborates on the familiar Keynes-Hicks' idea of "normal backwardation" as a reflection of the cost of price insurance to hedgers—material borrowed from his earlier work. He gives reasons this formulation still holds despite the rising importance of long hedging.

Curiously, Burns does not examine the evidence for a downward bias in futures prices, which evidence should exist if the Keynes-Hicks formulation were vital. More important, he does not recognize that for most commodities, futures trading establishes spot-forward price spreads that embody market-determined prices for services required to handle, store, process, and/or transport commodities—a better documented phenomenon than most that are advanced in the chapter on futures trading. The implicit prices influence the organization of production and the structure of business enterprise, a proposition that is basic to understanding what futures trading in commodities is all about. This curious gap might be explained by Burns' professional grounding in financial (rather than commodity) markets wherein spot-forward spreads can have no such meaning.

A chapter on option markets explains their nature, origins, behavior, and benefits. Many ideas abound. Again, a notable gap is the idea that option contracts are particularly suitable to commodity producers who face great output risk.

A chapter on market regulation argues that controls should "assure that orderliness of market conditions and quality of a market's organization . . . are at a level warranted by the given market's liquidity" (p. 89), e.g., thin markets should receive no special regulatory attention. The influences of false rumor and destabilizing trading are not serious problems because most futures markets are quite liquid. Duplicative trading facilities could become a serious problem because they tend to reduce liquidity. Burns' greatest concern is that foreign governments might manipulate U.S. futures markets, and he considers remedies. An appendix discusses exchange rates, tax straddles, and equity futures.

Burns surely is right in saying that few studies have examined futures and option markets in a market development context. His idea-packed work, written while he was the chief research economist for the Commodity Futures Trading Commission, is indeed welcome. It will stimulate thinking in important and controversial areas. But, it suffers from one general weakness. Too few distinctions are drawn between statements that are pure conjecture, hypotheses suggested by limited evidence, and conclusions based solidly on objective observation. Hence, some readers will be misled on what we really know and others will dismiss too much as dogma of a free marketeer. Yet, well-informed students of markets should be able to pick their way through these traps and garner enough food for thought to make a reading of the monograph worth their time.

Crotty, Raymond, *Cattle, Economics and Development*. Farnham Royal, Slough: Commonwealth Agricultural Bureaux, 1980, xv + 253 pp., £18 from CAB.

This study focuses on the role of cattle and water buffalo in a variety of settings where these animals play a significant role in the rural economy and provide outputs with economic, social, and cultural significance. The basic theme is that the interaction of capitalistic institutions with communal grazing land results in overexploitation of land, resulting in the gap in animal productivity that exists between wealthy countries (DCs) and less developed countries (LDCs). This problem is accentuated by technology transfer from DCs, particularly medical practices which have increased the population of cattle and humans and has disturbed the delicate balance between man, herds, and grazing resources.

As a prelude to the model of decision making by cattle keepers, the author provides an introduction (chap. 1), a statistical review of livestock numbers and productivity (chap. 2), historical aspects of resource use and agricultural transformation in a variety of agrarian societies (chap. 3), and demand relationships for livestock products (chap. 4). The model, developed in chapter 5, consists of three activities, six resources, and four outputs. A Cobb-Douglas function is used to establish the productivity conditions which are solved for net revenue maximization using five nonlinear simultaneous equations. The next chapters apply the model to:

Region	*Grazing Situation*	*Major Products*
W. Europe, N. America, pre-WW II	Individual grazing	Milk
W. Europe, N. America, post-WW II	Individual grazing	Milk and calves
Latin America	Individual grazing	Calves
Africa	Communal grazing	Milk and calves
Southeast Asia	Communal grazing	Calves
India	Communal grazing	Milk

In this schema, individual grazing refers to individual land use rights and "calves" implies growing out calves for beef. The overriding problems of each of the last four systems are identified and analyzed using the model. The author convincingly argues the reasons conventional development and lending programs have had limited success and, in some situations, have exacerbated the fundamental imbalances. Specific examples serve to document the arguments and a case study in the appendix provides additional material. Recommendations center around (*a*) how to reduce grazing intensity to socially optimal levels through livestock head taxes, (*b*) how to allocate tax receipts to local communities to increase animal productivity, and (*c*) how to allocate cattle investments to achieve productivity and equity goals.

The general problem with the book is that Crotty, under the guise of providing historical and institutional background material, brings in too much extraneous material. Themes that keep reoccurring include agrarian aspects of Irish colonial history, the selective impact of capitalistic institutions on colonial societies, the center-periphery debate on Latin American underdevelopment, the extent of lactose intolerance in LDCs, human population theory, and the high price of straw in India. Also, in studies where vast heterogenous regions are lumped together, some errors of omission are inevitable. The sections on Southeast Asia and India are the worst in this regard. Some errors of logic, unsupported by empirical facts, also occur. Examples include statements that the more valuable land becomes relative to other resources, the less pressure owners have to use it efficiently (p. 92) and higher food prices in Latin America lead to increased political instability and less investment in, and production from, agriculture (p. 101).

The concluding chapter goes far beyond simply summarizing the wealth of analysis and region-specific policy prescriptions. Instead, Crotty blames most of the productivity and stagnation problems on trade and finance policy of DCs. This leads to recommendations that the United States import Latin American calves for fattening. One need only check the charges at the Fleming Key quarantine station to gauge that recommendation. The same problem holds for export of surplus calves from India to Japan and the Middle East which would, incidentally, reduce the international prices of feedgrains since these countries would then import more grain to fatten these calves. Using LDC cattle exports to bargain with OPEC on oil prices is also recommended, as is forcing the EEC to dismantle its Common Agricultural Policy to help potential calf exporters from Africa and India.

Despite these criticisms, most of the book represents a skillful blend of Crotty's extensive international experience, considerable analytical skills, and deep understanding of the essential problems of cattle production in LDCs. The result is an innovative set of models which allow the author to condense the complex systems and to come up with generally practical conclusions that illustrate clearly why LDC cattle production has not progressed and why so many cattle investment schemes have fared poorly.

The book represents a valuable addition to our knowledge of cattle economics, is a must for any researcher concerned with animal production in LDCs, and should be standard reference for international agencies contemplating entry into the complex world of man and his cattle.

Winrock International Livestock Research and Training Center

Fennell, Rosemary. *The Common Agricultural Policy of the European Community*. Montclair, N.J.: Allenheld, Osmun & Co., 1979, xi + 243 pp., price unknown.

It is surprising but true that no recent book or publication exists in English that explains in simple terms the apparent complexities of the Common Agricultural Policy (CAP). Rosemary Fennell has filled this gap with a useful book for the many whose professional work brings them into occasional contact with the CAP. The book is concise, easy to read, and well-organized; it contains about as much factual information in 230 pages as one can reasonably expect. Separate chapters deal with European Community (EC) institutions, the legislative process, the financial arrangements, and that arcane topic, "green money." Market support mechanisms are described in three chapters—covering field crops, livestock, and horticultural products; and two particularly valuable chapters outline structural and social policy measures related to agriculture. A brief chapter on "enlargement" of the Community—the accession of Greece, Spain and Portugal—rounds out the book, though because the manuscript was completed before the end of the Greek negotiations for membership, this last chapter appears somewhat dated.

The author succeeds admirably in her limited objective of "explaining the rudiments of the policy" to act as "a base on which greater and more detailed knowledge can be built." The book does not set out to analyze either the policy in general or particular market instruments, and even avoids any reference to places where such analyses can be found. It is content to detail the "institutional and administrative organization" of the policy, leaving interpretation to the reader.

There are places, however, when even in a basically descriptive work some analysis can be useful, if only to distinguish the important from the trivial. For example, the listing of policy instruments for the various commodities in chapters 8 to 10 gives little information on which mechanisms actually are effective in determining prices in product markets. Although the author includes some useful diagrams showing the relationships among the various institutional prices set under the principal commodity policies, some simple charts showing how market prices have varied in relation to these administered price levels would have given the reader a better feel for the important aspects of the policy.

On the relatively few occasions when analytical statements creep into the text, they sit uncomfortably amid the descriptive passages. We learn, for instance, that "insulating Community farmers from world market influences" and providing them with "minimum levels of support achieved through the underpinning of prices" should lead to "an intensification of the comparative advantage of different regions" (p. 104). This smacks of the confusion that has bedeviled the CAP from its inception. While the removal of national protection would have had the effect of "rationalizing" production and also would have led to common prices, the setting of common prices at levels which support high-cost production and the buying-up of surpluses effectively prevents such adjustment. Though one could argue that this system is still "better" than if each country protected its own farmers, even that limited contention is of doubtful validity in a system where the national incentives to seek higher common support prices are so strong.

If such analytical statements creep in reluctantly and with limited impact, one has the impression that statements of opinion, equally rare, are struggling for inclusion but being carefully repressed by the author. They surface particularly in the chapter on institutions. "Little attention," we learn on page 29, is paid to the Economic and Social Committee by the Council of Ministers on matters relating to the CAP. "This is regrettable," sighs the author, "as its views are often well thought out." Opinions are free, and though this reviewer finds it difficult to reconcile this particular view with a recollection of the ESC as the author of some of the most wooly and equivocal documents in Brussels, such "asides" do not intrude. Indeed, a little more commentary might have helped to leaven an otherwise humorless topic.

One caution should be given to the reader. It is a conceit of the Brussels administration that the CAP is a straightforward, if elaborate, set of regulations spanning the Community and replacing national policy instruments. Fennell tends to perpetuate this myth. In fact, as CAP-watchers know, the "common" policy is riddled with national derogations, is unevenly applied among countries, and lives uncomfortably with national agricultural policies which in total absorb more government funds than the CAP itself. For the author to have attempted to describe this interaction with national policies—or indeed the way CAP regulations are implemented in individual countries—would have increased massively the size of the book. But again, some reference to these complexities would have helped the reader to put in perspective the "rudiments" of the CAP as given in the book.

These comments should not be taken as detracting from the clear merits of the book as an introduction to the CAP and as a convenient work of reference for the bookshelf. Nevertheless, as I am sure the author would agree, there is still ample scope for other books to explain, analyze, and interpret the CAP to the profession. The European Community is a dominant power in world agriculture: a better understanding of its operations can do nothing but good.

Franke, Richard W., and Barbara H. Chasin. ***Seeds of Famine: Ecological Destruction and the Development Dilemma in the West African Sahel.*** **Montclair, N.J.: Allanheld, Osmun & Co., Universe Books, 1980, xvi + 267 pp., price unknown.**

Seeds of Famine is a study of the political economy of historical and contemporary development in the Sahelian zone of West Africa. Franke is an anthropologist and Chasin, a sociologist. Their interest in the topic began in 1974 toward the end of a long and disastrous drought in the Sahel which began in 1968 and led to widespread hunger and famine. The book's audience is expected to be students, the general public, and scholars interested in the Sahel and the linkages between food production and the environment. Professional economists looking for analytical insights into the development process in the Sahel will be disappointed.

Franke and Chasin's (FC) thesis is that the deprivation witnessed in the 1968–74 Sahelian drought resulted from ecological destruction attributed primarily to the policies of the French colonial administration from the middle of the seventeenth century until 1960, when the countries gained their independence. FC's radical approach to understanding the causes of the drought rejects "single-variable" explanations, such as weather changes, desertification, overgrazing, mismanagement, population growth, and the "tragedy of the commons." Rather, the colonial system is indicted for destroying the beneficial interregional trade patterns which had been in existence between North Africa and the West African humid tropics since the days of the Ghana empire (500–1200 A.D.). The promotion of peanut cultivation by France in the eighteenth century led to growth in the area of cropland at the expense of pastures for animal grazing. The tax system established by the French also encouraged commercial cropping in order to earn the money necessary to pay the taxes. Degradation of soil resulted from the reduced fallow periods and forest areas and the demands peanuts placed on soil nutrients. Herders were forced to move animals further north toward the Sahara, thus breaking down complementary exchange relationships between farmers and herders in the Sahel.

Expansion of wells and watering points for herds after 1940 further exacerbated the problem by concentrating animals around them. Vaccination, animal health programs, and growing southern livestock markets led to a large growth in livestock numbers. "The peanut and the profit system were the real 'overgrazers'—not the nomads" (p. 99). These processes caused extensive ecological damage, and when the 1968–74 drought came, the frail ecology could not support the increased human and animal populations.

A feature of this book that detracts from its scholarly value is that many sources are newspaper reports and anecdotal material. Also, the tone is excessively emotional. The authors' analyses of the pre- and post-colonial eras are full of inconsistencies. These are epitomized by their statement about the effect on nomads of the introduction of ocean trade by the French: "The loss of the caravans was a severe blow to the nomads who . . . sometimes raided these caravans" (p. 67).

FC deplore the post-colonial dependency of Sahelian countries on the West for foreign capital investment and export markets, both of which they claim ensure the Sahel will become more vulnerable to future droughts. In a region where capital is scarce relative to land and labor, one wonders from where the Sahel could find the capital to invest in increased fertilizer use, which FC maintain is one of the major avenues for alleviating the soil degradation caused by peanuts. Many such contradictions permeate the book.

In rejecting "tragedy of the commons" explanations of the famine, FC imply there was little farmer/herder competition prior to the advent of the "capitalist ethic." No strong evidence for this is cited. Their arguments are made even less tenable by the statement (p. 122): "It was not simply herders and their lust for greater numbers of animals, but the pressures of the profit system that led to the overgrazing. . . ." The authors imply no profit motive existed before the colonial era. This is obviously not true as is clear from FC's own earlier descriptions of trade and commerce along the old caravan routes.

FC contend the large-scale projects being funded by the international community under the Sahel Development Program (SDP) in response to the 1968–74 drought are doomed to repeat past errors. They will ensure continuation of dependency relations and exacerbate the conflicts between cash cropping, food production, and herder interests. FC see conspiracies and capitalist plots behind many of the SDP projects. According to them, aid is being used to offset unequal trade relations, and the net result is that the populations are made no better off.

FC's solution to the development dilemma in the Sahel is for development to proceed from the bottom up via small projects instead of from the top down, as in the large-scale SDP projects. The mechanism for this is to be the formation of farmer/herder collectives based on the model of the Federation of Soninke Peasants in Senegal. This small non-SDP project seems to be the only project site the authors visited in their five months in West Africa.

The authors conclude the book by essentially advocating revolution by the citizens of the Sahel. Applauding the recent coups in Mauritania and Mali, they urge the formation of farmers' and herders' political and economic associations. "These nascent organizations . . . must eventually control the political and economic systems of entire Sahelian countries" (p. 237). The reader could be excused for being skeptical about this *non sequitur* for avoiding the adverse effects of the next drought.

The *coup d'états* instead could deliver the *coup de grâce* to the Sahel and its people!

J. G. Ryan
International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), India

Frankena, Mark W., and David T. Scheffman. ***Economic Analysis of Provincial Land Use Policies in Ontario.*** **Ontario Economic Council Research Study No. 18. Toronto: University of Toronto Press, 1980, viii + 171 pp., $7.50.**

This study is an economic analysis of the government's role in municipal and regional land planning in Ontario. The great merit of the monograph is that it brings together much relevant material. It provides a thorough survey of government intervention in the land market and a description of the legislation during the last two decades. Because Ontario statistics on land use are inadequate, the review of case studies dealing with the conversion of agricultural land to nonagricultural uses is most welcome. For the noneconomist, a valuable theoretical chapter outlines under what circumstances the land market fails to allocate efficiently.

Despite these merits, the monograph is disappointing in the analysis, and particularly so in the prescriptions. In their analysis of the conversion of agricultural land to other uses and its significance for food production, their data are suspect. Chapter 5 asserts that in the aggregate, the rate of conversion of land to built-up urban uses is low in relation to the rate of productivity increase in agriculture, the stock of agricultural land, and the decrease in the acreage of census farms. The productivity figures used are gross, including inputs produced on land outside Ontario, such as feed grains, calves, and heifers. The productivity increase of the major crops, including hay, in Ontario is considerably lower, roughly half the overall gross productivity increase. Moreover, closer inspection reveals that the rate of productivity increase is decreasing drastically. Since 1966, population growth in Ontario has exceeded the growth rate of total gross agricultural output.

The authors estimate that during the past decade about 1% of the good agricultural land was converted to built-up urban use. This is primarily based on a study of twenty-four urban areas with a population of 25,000 or over in 1971. What happened outside these areas in the form of losses to transportation and power corridors, power sites, water reservoirs, waste disposal sites, and new towns is ignored entirely. We are left in the dark, failing the availability of data, as to the cause and ultimate destination of much of the decrease in the acreage of census farms. Land becoming submarginal for agriculture is one explanation, illustrated by the tobacco example on pages 67 and 68, in which the authors incorrectly presume that the unit cost of tobacco production on lower quality land is necessarily higher than on prime land. Although the submarginality cause is plausible, particularly for unimproved land, it is not so obvious that the large decrease in improved land in the late sixties is caused mainly by this.

It seems that the authors have highly overestimated agricultural productivity growth on Ontario farmland, and underestimated the conversion of agricultural land to economically irreversible uses other than built-up uses in urban centres and rural nonfarm residential development. Although not explicitly stated, the message one gets is that much of the prevailing concern is unjustified. To call some of the discussion alarmist and cataclysmic rhetoric does little to bring economists, planners, and policy makers closer, which is what the authors hoped to accomplish.

The difficulties in performing the prescribed cost-benefit analyses are not elaborated. For example, how would the authors measure the benefits from rural nonfarm housing to find out whether or not a restraint policy should be implemented? Is it the maximum price potential residents are willing to pay to live in the rural area or the minimum amount they are willing to receive if they are excluded from that area? Moreover, how are they to be identified? Despite the absence of much of the necessary information and background, the authors insist that adoption of provincial guidelines or controls must be preceded by a cost-benefit analysis, since they feel that the burden of proof should be on the government. Because of these difficulties, many of those computations would be highly suspect. No cost-benefit analysis or other evidence is presented in support of the authors' doubts about the justification of many forms of government intervention in the land market, as the introduction promises.

The authors consider the maximization of national welfare as the exclusive objective of conservation policies. Because long time horizons, massive uncertainty, and economic irreversibility are involved, a better objective is to avoid future food calamities, even if their probability is small. It is impossible to quantify the benefits of such policies exactly, but their order of magnitude can be established. The cost of such an insurance policy is the decrease in national welfare, under the most probable conditions, imposed by the conservation policy. This decrease does not necessarily invalidate the policy as the authors conclude, but must be compared with its benefits.

University of Guelph

Friedmann, John, and Clyde Weaver. ***Territory and Function: The Evolution of Regional Planning.*** **Berkeley: University of California Press, 1980, 240 pp., $6.95.**

The authors present an historical perspective of regional planning by emphasizing particular indi-

viduals, schools of thought, governmental programs, and spillovers from other disciplines that they feel are noteworthy to the development of this field. Their basic thesis is that clarification of the "state of the art" in the evolution of regional planning doctrine is necessary to answer critics as well as to complement efforts involved in reexamination and reconstruction of planning philosophy. This is clearly indicated by such statements as "this . . . will help to throw regional planning doctrine into relief by revealing its origins, the options that were rejected, . . . alternative formulations that were neglected, and the new forms of doctrine . . . beginning to emerge" (p. 2).

Early in the book, Friedmann and Weaver point out two forces, territorial and functional, of social integration that they believe systematically surface in their reconstruction of the history of regional planning. The former relates to common bonds and the latter force to self-interest. The title of the book originates from these two components and this writer feels that such a label is misleading. First, the subtitle is more relevant to content than the main title, and second, it is not explicitly clear where each force is applicable and in what context during the various discussions.

The book is divided into three parts designated as regionalism in America, a spatial framework for capitalist planning, and the crisis in development, respectively. The first section contains some of the important social and intellectual changes that are interpreted as contributing to regionalism in our country. Discussion centers upon such events as urban industrialization, Theodore Roosevelt's conservation movement, impact of institutional economics, and the effects of governmental economic and social programs. The second section emphasizes theories of unequal and polarized development and policies to deal with residual areas. The final portion of the book explores the ramifications of the transnational movement upon regional development doctrine. The authors argue that as a result of transnational ideology reflecting functional power, there is a need to change regional doctrine to encompass more of the territorial (or common bonds) aspects of social integration. To accomplish this, Friedmann and Weaver lend support to a "basic needs" approach (termed "agropolitan").

The first two sections of the book are germane to the basic thesis of the book. The discussion generally centers upon the emergence of regional planning doctrine. It is the latter section which destroys the earlier success. The impression is given to this writer that the last part is written to resurrect the senior author's earlier original formulation of the "agropolitan" concept. The last section abruptly turns to regional development in developing countries. This sharp twist seems unrelated to previous material.

The authors should have enlarged the first two sections with additional focus upon current short-run influences associated with research and political trends that have a strong likelihood of affecting planning doctrine. The authors should have emphasized the analytical approach centering upon the importance of remote sensing and computer graphic techniques to their field. The influence of academic disciplines, i.e., environmental and community economics, upon regional planning is overlooked as well as the impact of the "less governmental intervention" or libertarian movement on this field.

This writer feels that the authors missed an opportunity to clarify the role of the engineer in the field of regional planning. The only time that the engineer is introduced into the book is in one short sentence where "the one . . . example of regional planning in practice, the TVA, was largely the handiwork of engineers . . ." (p. 92). Friedmann and Weaver should have described the complementing roles of the two professions as well as differences.

The authors obviously have an in-depth understanding of the literature influencing regional planning as illustrated by the many references contained throughout the book. In fact, Friedmann and Weaver introduce such a large number of footnotes at the end of each chapter that this writer became weary of turning pages in response to each note. Much of the information contained in the explanatory notes could readily be incorporated into the main text.

The advertising statements on the back cover designate this work as a landmark in the study of regional planning. It should be labeled a landmark in the sense that the authors should rethink, reorganize, and expand the existing effort to accomplish their original objective. The book, in its present form, falls far short of its intent.

Bruce E. Lindsay
University of New Hampshire

Halcrow, Harold G. ***Economics of Agriculture.*** **New York: McGraw-Hill Book Co., 1980, xiv, 383 pp., price unknown.**

The past few years have seen a spate of textbooks on the economics of agriculture for undergraduate students. Halcrow's contribution is slanted toward readers with little or no previous experience or knowledge in either economics or agriculture. It is intended as an introduction to more advanced courses in agricultural economics and to present an understanding of the major economic problems of agriculture to students in the physical and biological sciences, some of whom may have no idea of what agriculture is about.

The organization of the book appeals to this reviewer's biases and prejudices. There are ten fairly self-contained chapters. Each chapter starts off with a statement notifying the reader what the chapter contains. The exposition follows with clear,

simple definitions, in appropriate places, of rules, terms, and laws required for discussion of the subject. Discussions are well-illustrated with appropriate figures and tables, presented in a clear and straightforward manner. At the conclusion of each chapter is a concise summary of the material presented and a list of the important terms and concepts included in the discussion. This last serves a useful purpose for readers who might otherwise fail to recognize concepts as they read. It should save a lot of underlining in red pencil. Each chapter ends with a short statement about what is coming next and a list of questions and answers that should aid the student in reviewing the chapter.

The central economic problems of agriculture are listed and discussed early in the book. These are followed by a brief history of mankind's population growth since prehistoric times and its implications for the future of agriculture. Then follows a discussion of production functions and costs. This is pretty much limited to a discussion of single-variable inputs. Factor-factor, product-product, complementarity, and supplementarity are given light treatment consisting primarily of definitions and a brief discussion. Demand and supply and their elasticities are given rather thorough treatment. There follows a discussion of the competitive structure of agribusiness and production and marketing strategies of agribusiness firms dealing with meat and poultry, cereals, dairy, sugars, oils, and processed fruits and vegetables. Most of this discussion is descriptive. The chapter on farm income problems and programs discusses farm price and income problems and then describes past programs dealing with these problems from a historical and political perspective as well as in simple analytical terms. The final chapter deals with the historical development of international trade in farm products and its importance to American, as well as international, agriculture. Included is a brief discussion of the European Common Market and the Kennedy and Tokyo rounds to reduce international trade barriers. The book concludes with an excellent glossary of definitions of terms, rules, and laws used in the text.

The objectives of the text as stated in the preface are to begin with basic economic and agricultural concepts, develop a broad view of the central economic problems of agriculture and apply the concepts and principles to problem solving. It is in the final objective that delivery is not made. The author has done an excellent job presenting the central economic problems of agriculture and the basic concepts needed to solve those problems. But he does little to further a student's understanding of how the concepts discussed can be applied to problems of decision making by a farm firm or to formulation and implementation of public policy with regard to agriculture in the macro sense. Those who believe in use of concepts for analysis and decision making will miss the application of the concepts to such uses in the text. However, one text cannot be everything to all people. When it is realized that this text requires no previous knowledge of either economics or agriculture, one cannot expect a product covering all aspects of agricultural economics. If we place lack of development of analytical economic ability on the part of the student aside, this is an excellent text for students of limited background. In fact, there is no need to limit the text to students: it could be read profitably by any high school graduate who is interested in gaining some background about and insight into the economic problems of American and international agriculture.

Anthony P. Stemberger
Pennsylvania State University

Hicks, John. ***Causality in Economics.*** **New York: Basic Books, 1980, 124 pp., $8.95.**

This little book contains thoughts on methodology, the history of science and causality, and some words of caution about the use of probability in economics. Those thoughts and words come from the mind and pen of one of the more honored economists of the twentieth century. Therefore, they must be assumed to have some potential impact. I would like to take up some issues of disagreement in what must be a modest manner. Hopefully the theme and outline of Hicks' book may be filtered out of those comments.

Hicks says that economics is "on the edge of the sciences," and the central argument by which we are placed in those far suburbs is that true science develops propositions that are timeless. Their refutation (or lack of it) does not depend upon a time frame. In later chapters we are given Newtonian mechanics as an example of a set of scientific propositions that lasted two centuries before requiring modification for at least some sets of now observable data. Moreover, we are given a discussion of Adam Smith's propositions that wealth is concentrated near water transport. The point is that changes in technology (and technology is outside economic theory) may lead to a change in the truth-value of Smith's locational theory.

Borrowing from Hicks' own taxonomy of causation (chap. 2) and pondering his examples, we might draw the lesson that physics (at least, Newtonian mechanics) contains a great number of strongly causal relationships. In other words, *ceteris paribus* is not so crucial as it is in economics. This would enable us to interpret Hicks' use of the phrase "out of time" to mean that "time" is a shorthand for critical environment—all those things that must be held constant to make a meaningful causal statement. Certainly, one would not quarrel with the importance of the bundle of *ceteris paribus* for economics. We often yearn for strong causality, or at least costless experiments, which would provide dramatic evidence, for example, regarding the

proposition that doubling the money supply will, *ceteris paribus,* double the price level. To me, all this only says that economics is a difficult subject, differing in degree but not in purpose from other sciences. I get the impression that Hicks is saying more than this.

Alternatively, if we adopt the adage that "there is nothing new under the sun" for physical phenomena, one would find a significant point of departure. Economics is a social science, and societies evolve. However, as I understand modern notions of the universe, astronomers would feel no more comfortable with the adage than would biologists or economists.

Again, if one measures critical environmental constancy, or the lack of it, against real time, I would be prepared to believe that new phenomena may be more abundant in economics—a matter of degree. However, one must not give points away so quickly. The effects on scarcity of Diocletian price ceilings on food must have been much the same as more recent ones on natural gas. Similarly, coin clipping by Nero would have had some of the same effects as the Federal Reserve Bank buying bonds from the U.S. Treasury to finance the purchase of current goods and services.

Indeed, one wonders whether the crucial difference between economics and the "hard sciences" is because of so much change in the critical environment or whether it is because of the lack of "experimental data" due to little (or only slow) change.

Two of the crucial "experiments" of this century for economists in the industrial world of private ownership of capital have been the Great Depression, to which Keynes responded, and the inflation (together with unemployment) of the past ten years. Certainly there have been other "experiments" with inflation and recession in many countries, but the mass of theorizing and testing caused by the two events mentioned must dwarf the literature inspired by other events. It is my impression that economics as a science has responded to these new sets of data by revising its theories to account for the new data without countering the old. This is the response any science makes to new data.

The question of whether economics differs as a science is not at issue. The issue is whether the differences are so crucial that economics either does not qualify as a science or qualifies only as a poor neighbor. Given the recent decision by the current administration to let the entire National Science Foundation budget cut fall on economics, this rather nebulous and ancient issue evidently can be a crucial one. There may be unscientific economists, but economics is a study of mankind which seeks to develop hypotheses about human behavior, hypotheses that have empirical content in the sense that they are capable of being refuted. Therefore, economics is a science, and those who saw fit to include the discipline for Nobel awards showed good taste and common sense. Hicks never actually calls economics "unscientific" in his book, but he comes a bit too close to suit this reviewer.

Dudley Wallace
Duke University

Judge, George G., William E. Griffiths, R. Carter Hill, and Tsoung-Chao Lee. *The Theory and Practice of Econometrics.* New York: John Wiley & Sons, 1980, xxvii + 793 pp., $26.95.

This book covers most of the standard topics discussed in graduate econometrics courses and texts, with the notable exception of simultaneous equation models, a reasonable omission because the book is already long and because simultaneous equation models are well covered elsewhere. (Simultaneous equation models have been the subject of less recent work than many other topics covered here.)

The book is impressive as scholarship. There is a long list of topics for which the book provides the best textbook treatment currently available. For example, the book contains forty pages on heteroskedasticity, a topic often slighted in other texts, and it covers almost everything in the econometric literature on this topic. Other topics of which coverage is complete include autocorrelation, pooling of cross-section and time-series data, random coefficients models, unobservables, distributed lag models, and nonlinear models and related computational methods.

As would be expected, the book reflects the research interest of its authors. Thus there is an extensive discussion of pretest and shrinkage estimators (ridge regression and Stein-rule types), some of it with reference to multicollinearity, some not. There is also an extensive discussion of the related problem of selection of regressors. The discussion of the linear model under ideal conditions is cast in a decision-theoretic framework. My personal opinion that this is interesting in theory but useless in practice is obviously not shared by the authors.

It is typical in reviews of this type to search for minor flaws, to avoid the appearance of unquestioning approval, but it is difficult here because there is not much to criticize. The treatment of the linear model under ideal conditions is neither extensive nor clear, but the topic can be found easily in other texts. As noted above, simultaneous equation models are omitted entirely. One might also argue that time-series methods in general are not adequately covered.

In the preface, the authors state that the book is intended as a text and as a handbook or reference book for students or others. As a handbook or reference book, it has no serious competition—on the topics it covers, it is by far the best available. As a text, I expect it will be widely adopted in

courses for which two or more texts are used. As a sole text, it would be overwhelming for any but the most advanced, topics, courses. Precisely because the coverage is so encyclopedic, there is a tendency for standard econometric topics to become lost. (For example, a student might learn twenty ways to handle autocorrelation but miss the point that in practice virtually everyone uses the Durbin-Watson test and Cochrane-Orcutt transformation.)

While texts achieve varying degrees of financial success and critical acclaim, only the best constitute a service to the profession. This book is in that class.

Kada, Ryohei. *Part-Time Family Farming: Off-Farm Employment and Farm Adjustments in the United States and Japan.* Tokyo, Japan: Center for Academic Publications, 1980 (ISBS, Inc., Forest Grove, Ore., exclusive distributor), xv + 264 pp., $26.00.

This book reports on a comparative socioeconomic study of part-time farming in two samples of households, one from Wisconsin and one from Shiga Prefecture, Japan. The main hypothesis is that decisions of a farm family for taking off-farm employment are influenced by internal factors—stage in family life cycle, aspirations and goals of the family, quantity and quality of resource endowments—and external factors—off-farm employment opportunities, availability of additional farmland, and farm technology. The main method of analysis is descriptive within a typological framework. There is minimal application of economic theory to the labor supply decisions of farm household members and of econometrics. Thus, there is no serious statistical testing of a model of off-farm work participation or of supply of hours of off-farm work by farm household members.

Chapters 1–3 of the book provide an introduction to the study, a review of some of the international statistics and literature on part-time farming, and a comparison of structural change in U.S. and Japanese agriculture during the twentieth century. The comparison relies heavily upon the research by Hayami and Ruttan. Chapters 4–7 present the major findings. In this study a part-time farm family is defined as a farm household where one or more members engaged in off-farm work, including self-employment, for thirty days or more per year. The data for the analysis were obtained from interviews of 193 Wisconsin farm households and 245 farm households of Shiga Prefecture, Japan. Neither sample represents a probability sample of the respective geographic unit, so generalization would be difficult even if models were fitted econometrically.

In chapter 4, the topology of part-time farm families, which is used for classifying the farm households in later descriptive analyses, is presented. The classification considers the career pattern of the farm operator and the historical mobility of the family (for Wisconsin) or structure of the farm family (for Japan). The sample mean values of socioeconomic characteristics, including farm type, gross farm sales, net farm income, off-farm income, number of household members, number working household members, are presented for each of the typological classes.

Chapter 5 presents data mainly on subjective responses by typology class on motivation for off-farm work, kinds of on-farm and off-farm adjustments to facilitate dual jobholding, and conflict versus complementarity of dual jobholding. The chapter also presents data on who in the household participates in dual jobholding (i.e., who works greater than or equal to thirty days per year at farm and off-farm work). The reported frequency of dual jobholding is 62% for husbands and 16% for wives in Wisconsin sample farm households and 45% for husbands and 13% percent for wives in Shiga sample farm households.

Chapter 6 presents a description of time allocation of household members by farm size (acres) and farm type. It also shows the simple correlation of farm versus off-farm work of different household members. In chapter 7, the author attempts to give a life-cycle perspective to part-time farming. Households are classified by family stage, e.g., preschool, school age, etc. The main difference between U.S. and Japanese stages are due to the nuclear U.S. family system and the Japanese stem family, which is perpetual with family composition changing over time. Tables are presented showing labor input, family size, net farm income, off-farm characteristics, and type and size of farm by these family stages. Working time allocation seems to differ. In Wisconsin sample families, hours of farm work and off-farm work move inversely over family stages, but in Shiga households, they move together.

The author should be commended for his attempt to add to our knowledge about part-time farming. Unfortunately, the results do not go beyond being suggestive.

Hayami, Y., and V. Ruttan. *Agricultural Development: An International Perspective.* Baltimore, Md.: Johns Hopkins University Press, 1976.

Pearse, Andrew. *Seeds of Plenty, Seeds of Want: Social and Economic Implications of the Green Revolution,* New York: Clarendon Press, Oxford University Press, 1980, xi + 262 pp., $22.50.

Pearse and I have been green revolution watchers for over a decade. His views are summarized in the book under review; mine in a recent article (Dalrymple). Our perceptions generally differ quite sharply. I probably would not be his first choice as a reviewer.

The book is an overview of an earlier study known as Global Two, carried out between 1970 and 1974 by the United Nations Research Institute for Social Development (UNRISD). Pearse was project manager; he is currently Co-Director of the Participation Program for UNRISD.

Individual country studies were done by scholars representing a wide range of professions, particularly social science. According to Pearse:

> They sought to illuminate and explain the emergent situations at different levels and in different ways.
>
> Each used his or her own methods of research. No standardized instruments were insisted upon but it was made clear that field studies were required. . . .
>
> Most of the studies that resulted attempted to look at the introduction of the new technology in the context of one or several primary rural settlements. . . . (p. 2)

Altogether, sixteen bulletins were published and at least fourteen other manuscripts were prepared and/or issued between 1971 and 1977. A *Summary of Conclusions* was released in 1974, and a draft "Overview Report" was prepared in 1976 but not published. It was decided that "a more analytical and interpretative summary of the conclusions" was needed (p. viii).

The individual bulletins were a hodge-podge in terms of subject matter, approach, and presentation. They did share a preoccupation with the negative aspects of the green revolution and almost totally neglected its broader social contributions: (*a*) direct benefits to consumers beyond the producing village and (*b*) the indirect benefits such as the stimulus provided to multiple cropping and the multiplier effects on the economy. While it was assumed that the purpose of the technological changes was to provide freedom from food dependence on other nations and freedom from hunger (p. 3), very little attention was given these key issues.

The present book was largely shaped by this background. Had it been issued in the mid-1970s, it would have fitted in comfortably with some of the unbalanced literature of the time—which was much more concerned with the seeds-of-want aspect than with the seeds-of-plenty dimension.

But the book was not published until late 1980, and then it was not updated. A flood of literature has appeared on the green revolution since the mid-1970s, but essentially none of it is noted or incorporated in the book. The green revolution matured during this period and so did much of the writing about it. Pearse's account, therefore, is antiquated.

Well, then, how does the book do as a product of the early 1970s? Not very well. Virtually everything that Pearse says about the green revolution has been said before, and better, both by himself (in *Summary of Conclusions*) and by others. Pearse's current text meanders and is unexpectedly tedious.

This is not to say, however, that some new material has not been added. Yet nearly all of it concerns the problems of technology as related to agrarian structure, land reform or tenancy, and the evils of market-oriented capitalist agriculture. Indeed, at points it seemed that I was reading a tract on "Tenancy and Technology." The green revolution often appeared more a pretext than the major subject.

Near the end, Pearse does turn to a more useful and topical, though hardly pathbreaking, discussion of appropriate technology (chap. 12). There he advocates what has in reality emerged over the past decade: the expanded development of technologies more suitable for the less well-endowed farmers.

Pearse concludes with a chapter in which he eulogizes peasant-based strategies followed in China, Taiwan, and Japan. All three, of course, had rather autocratic land reforms ("historic events larger than the agricultural sector," p. 243).

> Thus, the dynamic process of a fully capitalist development in the sector has been eliminated or kept under control, and the marginalization and "delanding" of the peasant majorities, with all its social pathology, political instability, and individual trauma, has been avoided. (p. 243)

Whether these additional insights were worth the long wait is highly questionable. More "interpretative" they are; more "analytical" they are not.

Despite my misgivings about the book as an assessment of the green revolution, it probably will sell relatively well. It has a promising pedigree, an attractive appearance, an enticing title, and a prestigious publisher. Unfortunately, the contents are not up to, nor even true to, the package. But few purchasers will be immediately aware of this.

It is a pity that the seeds of such a promising project bore such tardy, meagre, and twisted fruit.

Sanderson, Fred H., and Shyamal Roy. *Food Trends and Prospects in India*. Washington, D.C.: The Brookings Institution, 1979, xiii + 162 pp., price unknown.

Ray, Susanta K., Ralph W. Cummings, Jr., and Robert W. Herdt. *Policy Planning for Agricultural Development*. New Delhi, India: Tata McGraw-Hill Publishing Co., 1979, xiv + 237 pp., price unknown.

These two books provide carefully researched analytical accounts of the development issues of Indian agriculture, of interest not only to those involved with India's economic development but to all those who are concerned with policy research and planning in the developing countries of the third world. Because it accounts for one-third of the population of the third world, the prospects of policies and programs for agricultural development in India are of international concern.

An excellent overview of the study by Sanderson and Roy was provided in chapter 1. An assessment of the trends in food grain production and population growth in the past quarter century has been described as the "food-population crunch," which is the real problem to be tackled effectively by appropriate policies and action programs in India. However, Sanderson and Roy devote little attention to the population problem as such or to the interlinkages of agricultural development and demographic factors. Instead, they concentrate on presenting an analysis of the long-term trends in food grain production and examine the contribution of input factors affecting production of rice, wheat, coarse grains, all cereals, and pulses. However, in discussing economic factors affecting the trends in food grains in chapter 4, the authors have not provided convincing analysis to support their conclusion that "with a few exceptions, fluctuations in real prices and returns per hectare, and fluctuations in the grain-fertilizer price ratios, did not exert a significant influence on fertilizer use or on weather-adjusted yields." Unfortunately, this kind of empiricism could lead to wrong policy prescriptions and perpetuate the market imperfections. A good discussion of the institutional factors affecting food trends is given in chapter 5.

In the second part of the book, the authors attempt to project the probable demand for food in 1990 and 2000 and examine whether it can be met from domestic production. Even if one has any differences with the authors' calculations of returns from irrigation and fertilizer, one can reasonably agree that these two are key factors for achieving additional increases in yields of food grains in India.

The last chapter of the book is devoted to policy implications. The authors have correctly cautioned the policy makers that they should be careful in evaluating the alternatives. However, they also could have emphasized that monitoring and continuous evaluation of the impact of the policy decisions in relation to the objectives is also needed. The value of this book by Fred Sanderson and Shyamal Roy to students of agricultural economics would have been enhanced if they had provided an index and a bibliography to the literature cited.

The book on *Policy Planning for Agricultural Development* by Ray, Cummings, and Herdt provides an excellent historical perspective and analysis of the agricultural development in India. In part one of the book, the authors discuss the agricultural stagnation up to the end of British rule and development under planning after independence (1951–75). After this, the authors present the framework for agricultural development in India in part two of the book, which is divided into three chapters (4–6) dealing with the role of agriculture in stimulating Indian economic growth, policy strategies, and alternative growth scenarios that might result. The planning strategy for 1978–83 described by the authors in chapter 4 is unfortunately now of academic interest only, because of the dramatic political developments that took place in 1980. With the comeback of Indira Gandhi to power, the Draft Plan for 1978–83 has been abandoned and the new Planning Commission is preparing a Sixth Five-Year Plan for 1980–85. However, the policy strategy presented by the authors in chapter 5 will be relevant even under the new Gandhi regime.

From the population policy point of view, it is of interest to note that Ray, Cummings, and Herdt think that "a higher agricultural growth rate should also increase the possibility of accelerating family planning." This is based on the implicit assumption that higher agricultural production will improve nutrition, particularly for pregnant and nursing mothers and young children, and this will increase life expectancy by lowering chances of death during the first ten to fiteen years. However, this is a simplified and stylized approach to an important and complex demographic problem of developing countries like India. The authors could perhaps have drawn the attention of the readers of their book, in this context, to the literature dealing with the "new home economics," as Nerlove called it.

Part Three of the book provides an excellent analytical account of policy issues dealing with research and education; production input requirements; economic infrastructure, marketing, and rural centering; price policy; and equitable development.

Both of these books are timely and useful to policy makers and researchers, because India is entering a new phase of economic development and the issues require new analytical insights. These two books can stimulate the necessary thinking in the right directions.[1]

EDITORS: Professors S.N. Kulshreshtha and R.C. Nicholson, Department of Agricultural Economics, University of Saskatchewan, Saskatoon, Sask., Canada, S7N 0W0

The Canadian Journal of Agricultural Economics is published by the Canadian Agricultural Economics Society three times yearly in February, July and November. Requests for subscriptions or membership applications should be addressed to: The Treasurer, Canadian Agricultural Economics Society, Suite 907, 151 Slater Street, Ottawa, Canada, K1P 5H4.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in the manuscript has not been published, is not being published or considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in the manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of the manuscript gives the AAEA exclusive right to publish, to copyright, and to allow or to deny reproduction of it, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) must explain.
2. **Author's identification.** To protect their anonymity in the review process, authors should not identify themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text. No more than four co-authors will be listed on a published manuscript.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; it is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type all footnotes, double-spaced, on a page following the article. Footnotes should be only explanatory and not for citations or for directing the reader to a particular work. This information can be incorporated into the text.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of a sentence, a parenthetical reference is unnecessary unless page numbers or a date are needed. A style sheet on references and citations is available from the editor.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when a manuscript is accepted for publication.
12. **Page charge.** Major support for this *Journal* comes from page charges of $40 per printed page, or fraction thereof, payable by the supporting institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for payment are sent with galley proofs.

American Agricultural Economics Association

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to Sydney C. James, Secretary-Treasurer, American Agricultural Economics Association, Department of Economics, Iowa State University, Ames, Iowa 50011.

American Journal of Agricultural Economics

Volume 63 Number 4

November 1981

AMERICAN AGRICULTURAL ECONOMICS ASSOCIATION

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Ames, Iowa, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, James P. Houck, Department of Agricultural and Applied Economics, 332 Classroom Office Bldg., University of Minnesota, St. Paul, MN 55108

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Ronald A. Schrimper, Department of Economics and Business, P. O. Box 5368, North Carolina State University, Raleigh, NC 27650

Common Property Externalities: Isolation, Assurance, and Resource Depletion in a Traditional Grazing Context

Carlisle Ford Runge

Institutional alternatives to common property externalities are wider than argued by private exclusive property rights advocates. The "tragedy of the commons" is not a prisoners' dilemma, characterized by the strict dominance of individual strategies. The nonseparable common property externality is an "assurance problem." The assurance problem provides striking perspectives in analytical and policy terms. It redefines the problem of the commons as one of decision making under uncertainty. Institutional rules innovated by the group to reduce uncertainty and coordinate expectations can solve the problem of overexploitation. Rules come in many forms, and private property is only one.

Key words: common property, institutional rules, nonseparabilities, prisoners' dilemma.

Externalities lead to nonoptimal market allocations. The literature is filled with examples of "market failure" arising from the divergence of private from social cost (Bator, Coase, and Meade). The "tragedy of the commons" arising from grazing too many cattle on a given area of land has been widely noted as an important representative case of externality. The private benefit of grazing an additional head of cattle on a common range exceeds the private cost, because part of the cost is incurred by the entire group engaged in grazing. As a result, individuals have an incentive to "free-ride" and resource overexploitation results (G. Hardin).

The example of a common property externality is only one of a large number of structurally similar problems. These include overexploitation of common fishing grounds, extraction of oil and natural gas from a common underground reservoir, deforestation of common lands for fuelwood, depleting underground water sources, and some pollution problems of common air and water resources (Dasgupta and Heal, pp. 73–78).

Economists have struggled to find appropriate analytic and technical tools to model these important problems. One is the theory of games (Von Neuman and Morgenstern, Luce and Raiffa). It has been widely and erroneously assumed that common property externalities arise for reasons associated with the famous "prisoners' dilemma" game. This paper will demonstrate (*a*) that such an assumption is a false interpretation of the problem and (*b*) a correct game-theoretic formulation of common property externalities. This formulation is known as an assurance problem (Sen). Assurance problems have interesting implications for institutional rules designed to halt environmental degradation. The discussion will focus on problems of overgrazing, with particular reference to pastoral grazing in developing countries. The analysis also will be extended to other examples of externalities and to public or collective goods generally.

Overgrazing: Some Theoretical Approaches

In much of the developing world, common property provides a complex system of norms and conventions over individual grazing

Carlisle Ford Runge is a former graduate research assistant, Department of Agricultural Economics, University of Wisconsin-Madison, now an assistant professor of public and environmental policy, University of North Carolina-Chapel Hill.

Research funds were provided by the Graduate School of the University of Wisconsin.

The author has benefited from comments by Daniel W. Bromley, Richard Bishop, Chris Nunn, Charlie Adelberg, David Lee, Kerry Smith, Gerald Marwell, and the reviewers of this *Journal*.

rights, closely resembling the traditional, common property institution of prefeudal Europe. Common property was an old Teutonic institution, which slowly gave way to the forced enclosure movements of the fifteenth and sixteenth centuries, notably in Great Britain. Its existence may be traced to Graeco-Roman times (Vassberg, Blum). Historically, and in its modern version, common property provides regulations of considerable complexity over individual grazing rights. Given its persistence, common property is argued by some scholars to be a relatively stable system (Dahlman).

As an institution, common property is distinguished from free and open access, where there are no rules regulating individual grazing rights (Ciriacy-Wantrup and Bishop). Often, what appears to the outside observer to be open access may really involve tacit cooperation by individual users according to a series of rules. This is common property. As in duopoly, a structure of use-rights to common range may be stable or unstable. It is this problem, not open access, which I will address. Empirically, it is important to distinguish between open access and common property if appropriate policy is to be formulated. The problems of open access arise from unrestricted entry. Problems of common property pertain to use-rights by a group of a given size.

Although common property may be a stable pattern of resource use in traditional societies, population growth, technological change, or rapid climate change can destabilize traditional institutions. Today, especially in areas of the Sahel and southern Africa, the breakdown of common property institutions has led to serious overgrazing (Hitchcock, Picardi and Seifert, Glantz).

Many economic consultants and planners have called for the imposition of private property rights to halt this "tragedy of the commons" (Johnson, Picardi). Following the tradition of enclosure of common grazing lands, efforts have been made to impose private property schemes to "internalize" a common property externality (Foss). Many have failed seriously. Not only have they failed to stop overgrazing, they also have contributed to further inequality in already unequal distributions of wealth. Lands formerly held in common are being transferred to individuals, such as high-ranking government bureaucrats, who can exercise influence in the allocation of use-rights. These individuals often fail to protect range quality (Hitchcock). An analysis of the economic paradigm leading to this failure sheds light on the problem.

The Property Rights Paradigm

Some economists argue that the proper solution for overgrazing a common range is to internalize its costs by making the public aspects of the range private. Instituting a scheme of such rights, if they are properly enforced, will create a market in the private rights to graze. This approach has led Demsetz, among others (Cheung, North and Thomas, Furubotn and Pejovich) to argue that the mere existence of common property rights over a scarce resource will lead to a tragedy of the commons because of the failure to internalize the social costs of grazing the last head of cattle. They argue that the enforcement of private use-rights to the resource will yield internalized costs to each user equal to benefits in total and at the margin.[1]

There are three things wrong with this analysis. First, it does not distinguish between situations of open access (in which the main difficulty is unrestricted entry) and those of common property.[2] This view implies the inevitable overexploitation of common property, an historically false position (Dahlman). Second, it treats the common property externality as if each individual's choices are independent of their expectation of others' choices. Thus, cost functions for each cattle owner are assumed separable in their arguments. Third, and most important, because individuals are assumed to act independently, the property rights paradigm abstracts from the crucial problem of each person's uncertainty about the actions of others.

The first of these problems is empirical. The next two are theoretical and require further elaboration. This may be provided with the

[1] The inherent inefficacy of common ("communal") property regimes in the property rights paradigm is expressed clearly by Demsetz. Demsetz asserts the "great disadvantage" of common property, since "the maximization of the value of communal property rights will take place without regard to many costs, because the owner of a communal right cannot exclude others from enjoying the fruits of his efforts and because negotiation costs are too high for all to agree jointly on optimal behavior" (p. 356).

[2] North and Thomas (p. 234), for example, describe the economic state of traditional pre-agricultural societies as one in which "[T]he natural resources, whether the animals to be hunted or vegetation to be gathered, were initially held as common property. This type of property right implies free access by all to the resource" (p. 234).

familiar prisoners' dilemma game. Its logical similarity to the common property approach in the property rights paradigm highlights the shortcomings of the latter in analyzing externality problems. The prisoners' dilemma, when generalized to more than two actors, is also known as the isolation paradox. The basic result is that collective decisions by independent actors produce inferior outcomes, unless an enforceable rule is imposed from outside the group. To the property rights school, this rule involves private, exclusive use-rights to the resource.

The Isolation Paradox: Independent Choice

The prisoners' dilemma is illustrated in the following gain-loss table.

First Prisoner	Second Prisoner	
	Not Confess	Confess
Not Confess	(1,1)	(10,0)
Confess	(0,10)	(5,5)

"Confess" or "not confess" represent the choices (or strategies) open to each of two prisoners. The ordered pairs indicate the number of years in prison which will result from a particular coincidence of choices. Imagine that the the prisoners are interrogated independently. Both know that if neither confesses, they will receive short sentences and spend a year in prison (1,1); if one confesses and turns state's evidence, he will be released, and the other will receive a heavy term of ten years (1,10), (10,0). If both confess, each gets five years (5,5). Assuming mutually distinterested motivation, the most reasonable course of action, represented by the pair (1,1), is unstable. To protect himself, if not to further his own interests, each has a sufficient reason to confess, whatever the other does. "Rational" decisions by each prisoner individually make both worse off. Even if communication between the individuals results in an agreement to observe choice (1,1), both have an incentive to break it (Sen). Even in repeated plays, the incentive always is to defect (Weintraub). Therefore, the noncooperative pair, (5,5), is a Pareto-inferior equilibrium.

Now imagine a community of N individuals who must graze cattle on a common range of fixed size. Each individual must choose to do one of two things. One is "stinting," or limited grazing on the commons. The second is grazing at a level which, while advantageous to the individual, ultimately results in exploitative overuse of the commons. If each individual formulates his grazing decision independently, the result is an N-person variation on the prisoners' dilemma. The cost of grazing to each individual is a function of the grazing decisions of all N individuals. If all cooperate and stint, then the common range is preserved and cattle remain healthy. Yet independently (even with communication), each individual has an incentive to defect and graze heavily in the near-term, overexploiting the range in the long run. Each individual believes that he will receive a higher profit if he grazes at an exploitative level rather than stints. The incentive structure is such that it does not matter which strategy the others choose. Therefore, grazing at an exploitative level strictly dominates stinting for each individual. Hardin, in his original article on the tragedy of the commons, wrote:

> The rational herdsman concludes that the only sensible course for him to pursue is to add another animal to his herd. And another . . . But this is the conclusion reached by each and every rational herdsman sharing the commons. Therein is the tragedy. Each man is locked into a system that compels him to increase his herd without limit—in a world which is limited. (Hardin and Garrett, p. 20; *Science*, p. 1244)

Curiously, it is individuals' independence that "locks them into" the tragedy. This is the same outcome Demsetz and the property rights school claim as the inevitable result of common property. The main features of this paradox are

(*a*) *Pareto-inferior outcome*. Each individual will choose independently to graze at an exploitative level, leading to a situation in which all are made worse off. All are led toward this noncooperative equilibrium.

(*b*) *Strict dominance of individual strategy*. The result of overgrazing arises independently of the expectations of each individual regarding the actions of others. Because the choices of each are logically independent, there is no problem of uncertainty about the actions of others.

(*c*) *Need for enforcement*. Even if an agreement is struck that specifies all will stint on the range, the strict dominance of individual strategy makes such an agreement unstable. Without compulsory enforcement imposed by an outside authority, any such agreement is unstable because each prefers

that the others stint while he defects and grazes exploitatively (Sen).

Even if individuals attempt to develop cooperative rules to enforce stinting they cannot resolve their problem because nobody has an incentive to keep such agreements. As a result, an enforceable rule must be imposed from outside. Institutional rules are viewed as exogenous to the problem at hand. Private property rights are consistent with this formulation because they can be imposed from outside, as with the parliamentary acts of enclosure. Because this approach starts from the (not always obvious) presupposition that individuals pursue strategies independent of the expected actions of others, the appropriate decision unit must be the private individual user. Also consistent with the strict dominance of individual strategy is the strong assumption that rational individuals will husband and conserve their own private range area at a rate consistent with the time preference of society as a whole.

If this formulation is correct, then only by imposing private property rules from outside can the group optimize its grazing. Any other alternatives are unstable because of the strict dominance of individual strategy.

This approach confounds situations of open access with those of common property, because its noncooperative assumptions leave no place for cooperative rules unless they are imposed and enforced from outside. The second objection is that this game structure treats externalities as if all cattle grazers behave like Robinson Crusoe. This implies "separability" of individual cost functions which, I will show below, is extremely implausible. The third, and crucial, objection is that by assuming the independent formulation of each individual's strategy, this approach does not deal with uncertainty regarding the actions of others. I argue that uncertainty is the major motivating force in overexploitation of common property resources.

External Costs: Separable and Nonseparable Cases

Imagine two representative cattle owners each of whom grazes cattle on a common range.[3] In a competitive situation, each individual cattle owner has a cost function for grazing on the common. They are

$$(1)\qquad \begin{aligned} C_1 &= C_1(q_1, q_2),\\ C_2 &= C_2(q_1, q_2),\end{aligned}$$

where C_1 and C_2 are costs to owners 1 and 2, respectively, q_1 is head of cattle grazed by 1, and q_2 is head of cattle grazed by 2. These owners are linked to each other through their individual cost functions which reflect external diseconomies of grazing. Increases in cattle grazed by 1 impose additional costs on 2, and vice versa. If each individual maximizes profits from cattle holding, they will equate price with marginal cost:

$$(2)\qquad p = \frac{\partial C_1}{\partial q_1} = \frac{\partial C_2}{\partial q_2}.$$

The welfare associated with cattle production on the common can be measured by the difference between social benefit and social cost. In a competitive situation, social benefit can be measured for the two owners by their total revenue,

$$\text{total revenue} = p(q_1 + q_2).$$

Social costs can be measured by total costs,

$$\text{total costs} = C_1(q_1, q_2) + C_2(q_1, q_2).$$

To maximize welfare, the joint profit function of the two individuals must be maximized, where π signifies joint profit, and π_1 and π_2 are the profit functions of the cattle owners:

$$(3)\qquad \begin{aligned}\pi &= \pi_1 + \pi_2,\\ &= p(q_1 + q_2) - C_1(q_1, q_2) - C_2(q_1, q_2).\end{aligned}$$

First-order conditions for a maximum are

$$(4)\qquad \begin{aligned}\frac{\partial \pi}{\partial q_1} &= p - \frac{\partial C_1}{\partial q_1} - \frac{\partial C_2}{\partial q_1} = 0,\\ \frac{\partial \pi}{\partial q_2} &= p - \frac{\partial C_1}{\partial q_2} - \frac{\partial C_2}{\partial q_2} = 0.\end{aligned}$$

Second-order conditions for a maximum are

$$(5)\qquad \frac{\partial^2 \pi}{\partial q_1^2} < 0, \frac{\partial^2 \pi}{\partial q_2^2} < 0, \text{ and}$$

$$\frac{\partial^2 \pi}{\partial q_1^2}\,\frac{\partial^2 \pi}{\partial q_2^2} > \left(\frac{\partial^2 \pi}{\partial q_1 \partial q_2}\right)^2.$$

An externality arises when either

$$(6)\qquad \frac{\partial C_2}{\partial q_1} \neq 0 \text{ or } \frac{\partial C_1}{\partial q_2} \neq 0,$$

[3] The exposition of separable and nonseparable externalities follows that of Davis and Whinston, although I have adapted their arguments to the case of profit-maximizing individual cattle grazers.

since (2) and (4) will not then coincide. Profit maximization by each individual will not give the greatest net social benefit possible because of the external effects of one's cattle on another's costs. For completeness, note that these external effects are diseconomies, so that

(7) $$\frac{\partial C_2}{\partial q_1} > 0 \text{ and } \frac{\partial C_1}{\partial q_2} > 0.$$

This much is standard.

A function is said to be separable if and only if

(8) $$f(x_1, x_2) = f_1(x_1) + f_2(x_2).$$

Consider the case in which the cost functions of the individuals are interrelated by external diseconomies but are separable in their arguments:

(9) $$C_1(q_1, q_2) = A_1q_1^n + B_1q_2^m,$$
$$C_2(q_1, q_2) = A_2q_2^r + B_2q_1^s.$$

Profit maximization is given by

(10) $$p = \frac{\partial C_1}{\partial q_1} = nA_1q_1^{n-1},$$
$$= \frac{\partial C_2}{\partial q_2} = rA_2q_2^{r-1}.$$

The key result is that each individual's marginal cost in the separable case is given entirely in terms of own cattle: q_1 for 1 and q_2 for 2. Davis and Whinston have shown that this result is formally equivalent to the strict dominance of individual strategy. Consistent with the noncooperative nature of the isolation paradox, if each individual formulates his decision independently, then his appropriate decision rule for profit maximization is "price equals marginal cost," as in (10).

A separable cost function leads to the same result as the prisoners' dilemma. Since marginal cost to each individual is defined entirely in terms of own cattle, then whatever the actions of the other individual(s), there is a unique number of own cattle that maximizes each individual's profit. This is no more than a restatement of the strict dominance of individual strategy. In sum, separability implies the dominance of individual strategy (Davis and Whinston).

The effect of separable externalities in grazing is simply to shift the total cost curve of any individual grazer by a constant equal to the magnitude of the external effect. Because marginal conditions are unaffected, the optimal number of cattle for each individual remains the same. A tax or subsidy scheme may then be used to correct the price system according to the classical prescription (Pigou, Meade). Davis and Whinston note that "the typical cases (of externality) with which the classical analysis has been concerned have, in fact, assumed the condition of separability" (p. 245). My purpose in treating separability in such detail is to show that approaches based on the strict dominance of individual strategy, such as the property rights paradigm, also assume separable individual cost functions.

When the assumption of separability is dropped, elements of interdependence and uncertainty are introduced which become difficult to handle with traditional tools and concepts. Because separability is formally equivalent to strict dominance of individual strategy, dropping separability implies interdependence of individual choice. Each individual bases grazing decisions on the expected actions of others.

Nonseparable Externalities

The joint use of a common grazing area is not a separable decision. Choices to graze cattle on a common range are not made by each owner in a vacuum. Rather, they are conditioned on expectations of the likely behavior of others. The common range has tied their welfare and decision making together (Netting, Rhodes and Thompson). In the nonseparable case, the externality enters the cost function of each individual in a multiplicative rather than an additive way, so that

(11) $$f(x_1, x_2) \neq f_1(x_1) + f_2(x_2).$$

For example, consider two cost functions for representative cattle owners of the following form:

(12) $$C_1(q_1, q_2) = A_1q_1^n + B_1q_1q_2^m,$$
$$C_2(q_1, q_2) = A_2q_2^r + B_2q_2^tq_1^s.$$

Profit maximization by each individual implies that

$$p = \frac{\partial C_1}{\partial q_1} = nA_1q_1^{n-1} + B_1q_2^m,$$

as well as that

(13) $$p = \frac{\partial C_2}{\partial q_2} = rA_2q_2^{r-1} + tB_2q_2^{t-1}q_1^s.$$

In contrast to the separable case, marginal cost is affected here not only by the variable under control of the individual, but also by the other's choice variable. Because each person's marginal conditions for profit maximization are affected by the grazing decisions of others, there is no well-defined decision rule for each individual. Externalities will not simply shift total cost by some constant, as in the classical, separable case. Instead, it is likely that the changed marginal cost to each individual caused by the actions of others will alter the slope of the total cost curve along its entire length. This is more plausible. We would not expect that grazing on a common range of fixed size would involve a constant externality independent of the number of cattle put on the range. One cattle owner's decision to graze cattle generally will depend on his expectation of the behavior of others.

In game-theoretic terms, this strategic interdependence implies that the strict dominance of individual strategy no longer holds. Each individual must take into account the actions of others in his decision to graze cattle on the commons. This defines the problem of the commons as decision making under uncertainty. This uncertainty, arising from the interdependence of choice, suggests a logical structure different from the separable case. Nonseparable externalities imply an alternative game structure.

In nonseparable choice problems, there is no unique solution for each individual. Because of the interdependence of choice and the resulting changes in the marginal conditions for profit maximization, the classical tax-subsidy solution breaks down because of the "twists" likely in the total cost curves. The presumed advantage of private property, which is rooted in the strict dominance of individual strategy, can no longer be justified on these grounds. Strict dominance no longer holds. In the nonseparable case, the imposition of private property is an attempt to impose separability on an inherently nonseparable externality. If it is to succeed, it involves creating a set of independent agents out of a community of individuals. While this may be one possible solution, the absence of strict individual dominance does not commend it as the only one. And the transactions costs likely to be incurred will not be trivial. Advocates of independent decision making may promote more costly responses to externalities than necessary by neglecting the interdependencies which exist.

Hence, nonseparabilities suggest that the main problem of common property externalities is uncertainty. This view is held by Dasgupta and Heal, who note that, "contrary to what is often claimed, the problem of 'the common' and the resulting suboptimality of the market equilibrium are *not* formally identical to an N-person version of the prisoners' dilemma game" (p. 59). They also argue that the N-person prisoners' dilemma is erroneous because it is characterized by dominant strategies by each agent. Properly formulated, the commons problem involves the interdependence of agents, such that it is in the interest of each to restrict output (to stint on the range) if that is the only way to get other agents to do likewise. Hence, "the guilty party is not the profit motive per se. Rather, it is the economic and legal environment in which the profit motive is allowed free play" (Dasgupta and Heal, p. 63)

This renewed emphasis on the economic and legal environment places the problem in an institutional context. It also permits reformulation of the problem of the commons. This problem of cooperation, in game-theoretic terms, is known as the "assurance problem."

The Assurance Problem: Interdependent Choice

The assurance problem (Sen) is an amended version of a game called "the Battle of the Sexes," discussed by Luce and Raiffa and Bacharach. This two-person cooperative game has the following payoff matrix, representing the gains and losses of two individuals. The man wishes that they go together to the dog races; the woman wishes that they go to the ballet. But each of them prefers to go together to either of these activities rather than to separate entertainments. This game of pure strategy pairs has two equilibrium points, both going to the ballet or both going to the dogs.

Man	Woman	
	Ballet	Dogs
Ballet	(1,2)	(−1,−1)
Dogs	(−1,−1)	(2,1)

The game is not one of conflict, like the prisoners' dilemma. It is a cooperative game

because there is no dominant strategy for either individual. Hence agreements, once made, contain no incentive to defect; both parties gain from adhering to the rules. The problem is assurance regarding the other person's intended action. The man and woman must correlate their expectations and cooperate through some rule which assures them that wherever they go, they will go together. The payoff matrix may be expressed graphically (fig. 1).

The shaded portion of the graph describes the outcomes which the individuals can achieve without cooperation by choosing their strategy independently, as in the prisoners' dilemma. This shaded portion may be derived more formally so as to illustrate the distinction between the prisoners' dilemma and the assurance problem. By formulating "mixed strategies" of the two and their associated payoffs, it is possible to trace out the "convex hull" shown in figure 1. This convex hull illustrates the gains possible from cooperative rules providing coordinated expectations, or "assurance."

For example, suppose that she goes to the dogs and he picks at random from his two choices, as shown in the payoff matrix above. Then his and her payoffs are given in the graph by the line LJ. Say that she goes to the dogs

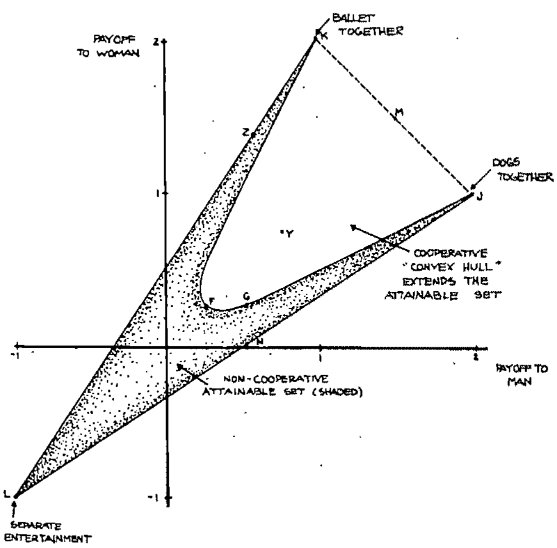

Figure 1. Payoff space: the battle of the sexes assurance problem

and he picks with probabilities half and half. His expected payoff is

$$1/2 \times 2 + 1/2 \times (-1) = 1/2.$$

Her payoff is

$$1/2 \times 1 + 1/2 \times (-1) = 0.$$

This gives the payoff pair of (1/2, 0), shown as the point N. Alternatively, suppose that each tosses an unbiased coin and goes to the dogs if it comes up heads. Then each of the four pure strategy pairs shown in the payoff matrix has a probability $(1/2)^2 = 1/4$. His expected utility and hers are the same:

$$1/4(2) + 1/4(-1) + 1/4(-1) + 1/4(1) = 1/4.$$

This gives the payoff pair (1/4, 1/4) at point F. The process can be continued with various probability combinations to trace out the convex hull. The important point is that when the choices of each are made independently, as in the prisoners' dilemma, it can be shown formally that the attainable set is only the shaded region of figure 1. This is the noncooperative attainable set.

However, cooperation enlarges the attainable set to include the entire area bounded by $LKJN$. In the assurance problem, the attainment of cooperative solutions such as point M requires coordinated strategies. These can arise only when the players' choices are interdependent and, recognizing it, the players devise a rule that provides assurance regarding the expected actions of others (Schelling, Bacharach).

The assurance problem provides a formal way of looking at interdependence and uncertainty associated with nonseparable externalities. Coordinated strategies evolve inside the structure of the game. In this sense, they mirror institutional rules which, by providing assurance, extend the set of possible solutions to allocation problems. By providing security of expectation, or assurance, reliable institutions are endogenous responses to the uncertainty of social and economic interaction (Taylor, Schotter, and Schelling).

Institutional Rules and Common Property Externalities in Grazing

The structure of the assurance game describes the problem of common property externalities in grazing. Its nonseparable character chal-

lenges the notion of strict individual dominance. It is more plausible to treat these externalities as problems of interdependence and uncertainty. Although Pareto-superior solutions may not be achieved, this structure—in contrast to the N-person prisoners' dilemma—does not make such solutions perpetually susceptible to defection and, therefore, inherently unstable.

The structure of the N-person prisoners' dilemma may be transformed into an assurance problem by dropping the assumption that individuals formulate their choices independent of the expected choices of others. When each individual expects everyone else to stint, that individual will stint, too. This has long been noted as an adaptive response in stable pastoral grazing economies (Brokensha, Horowitz, Scudder; Netting; Rhodes and Thompson). On the other hand, if each expects others to graze exploitatively, then each will also have reason to do so. In order to achieve the Pareto-superior outcome of range preservation through stinting, a coordinated strategy must be devised according to some set of rules or institutions.

Approaching overgrazing as an assurance problem provides striking perspectives in both analytical and policy terms. The strict dominance of individual strategy no longer holds. Consistent with the nonseparable common property externality, expectations of others' choices must be entered as a formal part of the determination of one's own choice. No individual can decide the preferred grazing strategy until it is known whether or not others will stint. A Pareto-inferior outcome no longer holds; if everyone is assured that the others will stint, then it is in their individual interest to do likewise. This outcome is not Pareto-inferior, since stinting is preferred by all in such a situation. If some assurance regarding the actions of others is provided, via an institutional rule, it is possible to achieve multiple equilibria in the extended "convex hull" of the attainable set. The lack of a dominant strategy for each individual cattle owner means that there are a variety of alternative solutions possible through cooperative action. Precisely which will be taken depends on individuals' bargaining power, their initial endowment of resources, their culture, climate, and so on. Analytically, the assurance problem's solution is an "equilibrium core" (Scarf, Shapley and Shubik). Unlike the prisoners' dilemma, cooperative solutions offer no incentive to defect. This suggests that institutional rules providing complete assurance are self-reinforcing; the incentive to keep them is that Pareto-superior solutions are attainable via cooperation which are unavailable otherwise. The key element determining the success or failure of institutions is therefore the extent to which they foster coordinated expectations (Ullman-Margalit).

It is hypothesized that the function of institutional rules is to parameterize expectations of the likely behavior of others. More precisely, "assurance" may be expressed in terms of the parameters describing—for each individual—the moments of a subjective probability density function over others' contribution to a public good. The moments of this function identify the expectation of stinting by others, the variance around this expectation, and the pessimism or optimism (skewedness) associated with it. Whether rational, self-interested individuals contribute to range quality by holding cattle off the range depends on the likelihood they attach to the level of voluntary contributions by others (Frohlich and Oppenheimer). The moments, notably the variance, of these density functions describe the level of assurance regarding these actions.

The virtue of institutional rules is that they are a relatively low-cost "shorthand" describing this expected behavior. Suppose that tribal tradition—the result of long-standing agreement—is such that each grazer is expected to stint at an arbitrary level (q^*). The result of this institutional rule is to formalize, for each grazer j, the expected actions of others at level q^*. Each expects the others to graze at level q^*, and, with this assurance, agrees to do the same (Brubaker). The rule extends the set of Pareto-superior allocations available to the tribe by preserving the range. Since communication and transactions needed to achieve cooperative institutional rules are not costless, agreement on the "shorthand" rule for grazing at q^* provides its own incentive to be retained as a tribal tradition.

A number of authors (Taylor; Frohlich and Oppenheimer; Frohlich et al.) have shown that an approach based on this interdependence of choice in the provision of public goods alters the conventional view of enforcement and the "size of the group." In particular, it challenges the well-known results of Olson, Buchanan (1968) and Russell Hardin, in which public goods, such as range quality, are seen as prisoners' dilemmas. These

conclusions, which depend on separability of individual cost functions, imply that expectations regarding the likely choices of others are not important, because for each, the strategy of not cooperating (i.e., exploitative overgrazing) is dominant. The only situation in which voluntary cooperation might be expected is when the group is small. Strictly speaking, even in small groups, the strategy of defection is still dominant without enforcement from outside.

If individuals' choices are interdependent, these results do not hold except under special assumptions about the shape of utility, cost, and production functions of the individuals (Taylor, Frohlich et al.). If expectations about the choices of others are relevant, then coordinated expectations are sufficient to generate voluntary contributions to a public good, independent of group size or outside enforcement (Frohlich and Oppenheimer, Marwell and Ames, Smith, and Bonacich et al.).

The relationship between the assurance problem and group size is that an individual's subjective estimation about the expected actions of others, notably its variance, generally would be expected to increase with the group size along with transactions and communications costs of finding an appropriate coordinating rule. But this is not true in every instance. The benefits derived from finding such a rule also might be expected to increase with the number of contributors, as would the opportunity cost of finding alternative rules.[4] The critical point is that institutions may succeed or fail whether the group is large or small (Taylor, p. 25).

A further point is the need for enforcement from outside the group. In principle, if institutions provide complete assurance, enforcement from outside the group is neither necessary nor sufficient for stable rules which insure nonexploitive grazing. A cooperative institutional rule providing complete assurance implies a total lack of uncertainty regarding the grazing behavior of others. Expectations are perfectly correlated, so that each individual's expectation of others' actions is concentrated around a particular level of grazing such as q^*. This is a limiting case, requiring perfect information and the absence of transactions and communications costs (Elster, pp. 20–23). These assumptions create a "perfect" solution to the assurance problem which is the institutional analogue to "perfect competition." In such situations, individuals have a sufficient incentive to contribute to range quality, without any need for outside enforcement (Frohlich et al., p. 328).

But what prevents someone from ignoring the rule at the expense of the others by "riding free"? The answer is that the benefits possible in the short term may be more than offset by costs arising within the group from breaking the institutional rule. In the absence of strictly dominant individual strategies, recognized interdependence makes the costs of reputation loss high. Pecuniary costs imposed by the group on its own noncooperative members also may occur (Akerlof). "Not to be trusted" in one circumstance may lead to a general loss of reputation, much like losing one's credit rating. These costs, plus reductions in the attainable set if such antisocial behavior "sets a trend" for others, plus the opportunity costs of innovating new rules, may well exceed the expense of stinting on the range. Because defecting or free-riding is not a strictly dominant strategy, enforcement is not a logical necessity.

This does not deny that in cases in which strategies are imperfectly coordinated (for whatever reason), enforcement from outside may help to achieve Pareto-improvements. For example, if cooperative agreements had led to a solution, such as point Y in figure 1, it might then be necessary for some enforcement from outside the group to move beyond point Y in the direction of line KMJ. This enforcement level would be significantly less than that required in a noncooperative environment. By allowing individuals full cooperative play, enforcement costs may be reduced. After exhausting cooperative rule-making potential, it may then be necessary to bind people by recourse to outside rules. But one should not jump, as in the prisoners' dilemma, to the conclusion that all such rules must be imposed and that people are not capable of binding themselves, like Ulysses, for their mutual benefit (Elster). The lesson of the assurance game is to let individuals have full freedom to innovate self-binding rules which best serve their needs before enforcing rules from out-

[4] Buchanan (1968, p. 91) was forced to conclude that "during period of extreme stress, such as was apparently evidenced by the British during World War II, behavior characteristic of small groups may have extended over almost the whole population." Smith concluded from an extensive series of recent experiments in public goods provision that "there appears to be no systematic effect of collective size or experience on the quantity of the public good provided" (p. 592). Similar results have been reported by Marwell and Ames, and Bonacich et al.

side. Rules will be better suited to the needs of the group (whatever its size) and more likely to succeed if based on this premise. These rules may come in many shapes and forms, not all of which are familiar. The institutional opportunity set of solutions to externalities is much wider than we think, and private property is only one.

Finally, enforcement from outside the group is not a sufficient condition for preservation of a public good such as range quality (Frohlich and Oppenheimer). The problem is that there is nothing to prevent the enforcing authority from abusing its position and putting control of land in the hands of a favored few with no interest in preservation or range quality. Any enforcement mechanism operating from outside designed to coerce provision of a public good must invoke a higher authority for its legitimacy. But this legitimacy is also a public good. Land grazing may be privately held and land titles enforced, but the "free-rider" problem will remain without cooperative institutional rules providing assurance within the group.

Conclusion

The assurance game suggests that cooperative institutional rules are endogenous adaptive responses to the problem of uncertainty about the expected actions of others, and that enforcement from outside is a second-order solution if these cooperative strategies are ineffective. The occurence of inferior outcomes, such as overgrazing, does not necessarily arise from the strict dominance of independent individual strategy. Rather, overgrazing results from the inability of interdependent individuals to coordinate their actions. In the pastoral grazing context, population growth, technological change, and climate changes make all such coordinated action more difficult than in more static settings.

Although I have focused on the role of institutional rules and assurance in problems of overgrazing, there are other common property externalities in which assurance problems may be even more important. With underground oil, coal, natural gas, or water, or with problems of air or above-ground water pollution, or with fisheries, it is simply infeasible to impose private property schemes since the common resource pool cannot be divided into discrete pieces. In these cases, the role of cooperative institutional mechanisms providing assurance takes on additional significance.

A key issue in this discussion is the way in which individual choice is modeled. Whether individuals are independent or interdependent is an empirical matter, but it is not without implications. Although everyday experience supports the interdependent view, the notion of "methodological individualism" has sometimes been used to support the argument that man is an independent actor, like Defoe's Robinson Crusoe. This view has deep intellectual roots, stretching back to Hobbes, and even earlier (Gonce). Yet Hayek noted that:

> Far from being opposed to voluntary association, the case of the individualists rests, on the contrary, on the contention that much of what in the opinion of many can be brought about only by conscious direction can be better achieved by the voluntary and spontaneous collaboration of individuals. The consistent individualist ought therefore to be an enthusiast for voluntary collaboration—wherever and whenever it does not degenerate into coercion of others or lead to the assumption of exclusive powers. (p. 16)

Traditional analysis, treating social choice as the product of aggregated independent individual choices, is given a much richer interpretation through the assurance game. Yet as Mishan noted in his survey of the externalities literature, "economists respond to the real world with a time lag, initially making use of more familiar, if less relevant, bits of apparatus" (p. 1). The familiar assertion of the strict dominance of individual strategy, reflected in the prisoners' dilemma, needs to be replaced with a richer framework.

This is not an argument against private property rights. Such rights may be an entirely appropriate institutional form, especially in societies based on the law of contract. But they are not the only institutional alternative nor the best in all circumstances.

The property rights paradigm, predicated in strictly individual strategies, misdiagnoses the grazing problem. By failing to recognize the endogenous character of property institutions caused by the interdependence of choice, it supports solutions which may be poorly suited to traditions of pastoral grazing societies. By seeking institutional rules imposed and enforced from the outside, it has promoted costly, top-heavy institutional regimes which restrict the potential for cooperative action. One example of such cooperative action is common property. The strict dominance of

individual strategy leaves no place for such solutions.

In the rapidly evolving economies of the developing world, a palpable uncertainty grips efforts to solve problems of growing populations and stagnant agricultural production. Traditional common property institutions may no longer suffice. However, efforts to impose institutions even more alien to the traditional, cooperative rules of a society may be profoundly destabilizing. If private property regimes fail as a solution in these societies, it is because they do not solve the problem of assurance.

Such assurance may require a decentralized approach to institution building based on the institutional norms and conventions of traditional cultures. Cooperative solutions are most likely to succeed where the locus of decision making is a relatively small, cohesive body. This is so, not because of the "size of the group" per se, but because assurance about the actions of others is largely a matter of information conveyed via transactions and communication. Information, organized as a set of rules, reduces uncertainty. In a larger sense it is information, rather than capital, that is the scarcest factor in rapidly changing agricultural societies. The free flow of information, and cooperative institutions which promote it, are most likely to occur at a relatively decentralized level.

Of course, enforced regulation from outside may still be needed. Since enforcement is expensive *vis-à-vis* voluntary cooperation, it should be a second-order solution.

It is ironic that the Hobbesian view of man's fate as a "war of all against all," so deeply imbedded in a strictly individualistic interpretation of economic choice, should lead property rights advocates to conclude that solutions to overgrazing must be imposed from the outside. The isolation paradox should be carefully analyzed by development planners and aid donors who are bent on exporting institutional forms which are a product of our own extraordinary history.

Food Product Proliferation: A Market Structure Analysis

John M. Connor

The frequent introduction of avowedly novel products is a common marketing strategy of leading food manufacturers. Over half of all new packaged consumer goods are foods or beverages, yet little is known about the amounts, patterns, and causes of product proliferation. Alternative definitions and analytical models of product proliferation are reviewed, focusing on those derived from Hotelling spatial-equilibrium theory. A simple regression model is used to test the relationship of market structure to the number of new food products introduced. The results verify that food product proliferation is a mode of industry conduct arising from markets characterized by differentiated oligopoly.

Key words: food manufacturing, market structure, monopolistic competition, new product introductions, oligopoly, product differentiation, product proliferation.

In a recent *Journal* article, Padberg and Westgren chide agricultural economists for failing to analyze the important topic of new food product introductions. As they rightly argue, product proliferation is one of the major modes of competitive conduct by leading food manufacturers. Yet, little is known about the amount and patterns of new food product introductions. Even less is understood about how industry structure might affect product proliferation, but this is not surprising because structure-conduct links generally have received scant attention by economists (McKie). Not only may this dimension of conduct significantly affect economic performance, but also it may feed back on industry structure by increasing market shares of leading firms or by elevating barriers to entry.

Connor (1980b) has reviewed the reasons given by critics who regard product proliferation as one failing of the food system. First, they regard product proliferation as deceptive because most "new" products are mere imitations or minor variants on existing products and because they are marketed by the same few leading firms. Second, proliferation is said to exacerbate inflation because new products often have higher price/quality ratios than existing substitutes. Third, product proliferation entails waste in the forms of self-cancelling advertising, high failure rates, and suboptimal production levels. Fourth, the large number of new products introduced may undermine rational decisions by rendering trial purchase and evaluation difficult. Finally, product proliferation may be an anticompetitive strategy reinforcing product differentiation and raising barriers to entry.

While some food manufacturers might favor a nonproliferation treaty, they mainly regard new product introduction as an unequivocal benefit for their companies and consumers. Major firms think that new product programs are essential for firm growth, financially successful, and likely to become more important in the future (Hopkins). Manufacturers aver that product proliferation broadens consumer choice and, through market segmentation, satisfies consumer demand more precisely. Product introduction is equated with new entry; high failure rates are taken as evidence of strong competitive rivalry. (For a contrary view, see Abrams.)

Though few empirical studies exist, differing positions have been taken on performance implications of product proliferation. Abbott, for example, argues that product differentiation and product proliferation are superior

John M. Connor is head of the Food Manufacturing Research Section in the Economic Research Service of the U.S. Department of Agriculture.

The views expressed in this paper are not necessarily those of the agency.

Two research assistants with the Food Systems Research Group of North Central Research Project NC-117, Michael Pratzel and John Brogan, assisted in the development of these data. The author is indebted to Richard Schmalensee, Bruce Marion, James Zellner, John Culbertson, and three anonymous referees for many constructive comments.

substitutes for price competition with homogenous goods: "Non-price competition enhances the competitiveness of markets unless it is accompanied by barriers to imitation or by deceptive or diversionary advertising techniques" (p. 113). On the other hand, Scherer's (1980) summary judgment is that in markets where the proliferation of higher priced variants is the dominant mode of conduct, "more product variety is apt to materialize than the amount that maximizes social welfare" (p. 260).

This paper examines the extent of product proliferation among manufactured food products, its relationship to the market structure of the food-manufacturing sector, and some empirical determinants of new food product introductions. Economic theory suggests that product proliferation is an expected outcome in industries displaying a lack of "hard" or price competition. A model is tested to demonstrate that departure from competitive market structures are conducive to high levels of proliferation among processed food product classes. Finally, there is a brief discussion of the implications for consumer welfare.

The Concept of Product Proliferation

The term product proliferation is rather new and variable in usage. In this paper I use the terms "product proliferation," "new product introductions," "new product development," and "product-space packing" more or less interchangeably. (This usage is consistent with Scherer's 1980 revised textbook.) A common concept underlying most discussions of the subject involves a spatial analogy. That is, any given item can be categorized according to several attributes or dimensions; each dimension defines a product-attribute space that usually holds some empty or unfilled segments. Product proliferation consists of "filling" or making the space denser.

Product proliferation can be thought of as either a stock (state) or flow (rate). First, for a given well-defined market at a point in time, the level of product-space packing could be measured by a count of the number of variants in distribution or that number normalized to market sales. Second, product proliferation can be conceived as the gross or net flow of product variants into a market over a span of time. The number of new products introduced (possibly net of disappearances) could be expressed as a ratio by dividing by either the number of existing variants or total market sales. In this paper I generally use the gross rate concept of product proliferation.

This spatial concept can be used to distinguish "commodity-type" foods from physically "highly differentiated" foods. Products needing more dimensions to define them completely are more differentiated. For example: raw cow's milk reached the urban consumer of the early nineteenth century with only three or four dimensions (color, creaminess, freshness, and possibly water content). Milk was unpasteurized, unpackaged, unflavored, and unavailable in multiple butterfat levels. It had multiple end uses. Today, milk is more differentiated because, in addition to being branded, it is packaged in three or more sizes, three or more butterfat levels, and plain or chocolate flavored. As a result, most grocery stores carry at least a dozen fluid milk items. In addition, milk is now available in canned and dried forms that have more limited uses. Although fluid milk has been subject to modest product proliferation in the last one hundred years, it remains among the least differentiated of processed foods.

More differentiated products exhibit as many as ten dimensions. The attribute axes can be either continuous (e.g., sweetness) or discrete (e.g. type of packaging). For example, to adequately identify a particular ready-to-eat breakfast cereal the following information is needed: (*a*) basic ingredients, (*b*) preparation method, (*c*) shape and color, (*d*) organoleptic properties, (*e*) flavorings, (*f*) packaging, (*g*) time of manufacture, (*h*) intended occasion, (*i*) dietary characteristics, and (*j*) reference or target group. Though some of these dimensions may be irrelevant for a specific food, the ten characteristics should fully specify most contemporary food products. For each segment of the product-attribute space, there is a corresponding segment of potential demand. Changing any of these descriptors, especially the last three "psychic" attributes, implies a change in the demand segment to which the product corresponds. If a cereal is presweetened by frosting the flakes, then it could be re-aimed at another potential consumer group, young children perhaps. Reformulation implies a shift in the identity of close substitute cereals. The "repositioned" product would now compete in the "presweetened children's" segment rather than the "low-sugar adult" category.

Product proliferation is intimately related to the state of the arts. With a constant stock of technology and fixed demand, the introduction of physically differentiated products eventually would cease. In such a stationary world every available segment of the product space would become fully exploited and no additional products could be profitably introduced (Eaton and Lipsey 1975).[1] Technological change, however, can expand the product space by making additional dimensions possible, by adding more classifications on existing discrete axes, or by extending the range of continuous axes. Thus, technological change can be said to be a sufficient condition for product proliferation. It is not a necessary condition, however, because some physical differentiation (e.g., changes in package size) can occur with a static technology.

To illustrate, consider changes in kitchen appliance technology. The advent of the freezer led to the frozen replication of most canned goods. Microwave ovens imply the appearance of microwave-compatible foods and food packaging. Retortable pouches will permit another wave of proliferation. In these cases, technological innovation was a necessary condition for product proliferation, but consumer acceptance had to be won by convincing users of the inherent convenience, increased palatability, or compactness provided by further processing.

In addition to proliferation due to physical changes, persuasive advertising can create subjective perceptions or psychic differences among products (see Connor 1981). Advertising especially can alter the intended occasion, special identity, or target group of an existing product. The increasing importance of psychic satisfaction relative to physical needs appears to be related to affluence (Galbraith).

By dropping the fixed-demand assumption, product proliferation can occur even with a depleted technological reservoir. New demand for a particular segment of a product-attribute space can be generated by changes in income, demographics, or taste. Rising incomes may reduce consumer resistance to new products, most of which are higher priced than existing close substitutes. Smaller families, increased education, and more dual-career households probably have encouraged the introduction of smaller package sizes and convenience foods. Finally, many new food products have been marketed to satisfy consumer interests in low-calorie, "natural," ethnic, gourmet, and snack foods. Although the influence of demand on product proliferation is undeniable, it can be overrated easily. The mere availability of a new product creates some interest in it. Furthermore, new product promotion can shape household preferences. Thus, satisfactory analysis of product proliferation may require models that allow for simultaneity among supply and demand factors.

Packaging changes may be the most prominent form of food product proliferation (Arthur D. Little). It is certainly one of the most obvious. Packaging permits food manufacturers to offer multiple units and a nearly infinite gradation of sizes. More important, packages can deliver messages indicating possible use, occasions for use, and the appropriate reference group. Thus, purchasers can be told that a breakfast cereal also can be used as a snack or baking ingredient. Packaging changes can induce product proliferation by expanding the supply space, altering corresponding demand segments, or changing the mappings between the two sides of the market.

Two other dimensions of product proliferation are brand and price. Neither necessarily implies physical differences in products, but either can create differences in the minds of consumers. Trademarks can serve to collapse several product dimensions for consumers. Thus, some trademarks like "Shredded Wheat" carry a nearly generic connotation for several physical characteristics. If alternative descriptions like "Woven Wheat Pillows" are unattractive, product proliferation in the ready-to-eat breakfast cereal market may be reduced. On the other hand, branding can facilitate product proliferation. An example of brand-driven proliferation is where manufacturers make multiple brands of the same products. This may occur when two regional manufacturers in the same industry merge. More commonly, private label products are manufactured according to precise retailer specifications, but when two or more retailers use

---

[1] Eaton and Lipsey extended the Löschian location model under the assumption that demand was evenly spread over the space. They demonstrated that entry (new product introductions) can always be forestalled if the space is packed densely enough; conversely, entry will always occur if the space is packed loosely enough. By relaxing the usual Löschian assumption of zero conjectural variation (i.e., they permit existing firms to have pricing reactions caused by entry), they derive equilibria that generate positive profits and barricaded entry that depend only on the density level.

the same specifications, then only the labels are different.

Within a well-defined category of products, there are likely to be fairly wide and sustained retail price differences, especially between national brands and first-line private label products. While many consumers use price as a guide to quality, a reasonably thorough review of evidence from laboratory tests and consumer taste panels found no such relationship (Parker and Connor). This is also confirmed by two formal analyses of correlations between price and quality ratings by *Consumer Reports* magazine for a wide array of manufactured products (Morris and Bronson; Swan).[2] Usually, wholesale price differences among the leading national brands of a given product are so slight that resulting retail-unit-price differences are nearly imperceptible to consumers. Some food manufacturers do use large price differences to create either a luxury or austere image for similar products. If they are extreme enough (e.g., "premium" and "superpremium" beers), two or more distinct product categories may be created. Mass-media advertising by food manufacturers is rarely used to inform consumers of suggested or actual price differences (Resnik and Stern; Stern, Krugman, Resnik). Of course, temporary discounts, specials, and other deals do create noticeable, if brief, price differences which may be highlighted in local retailer advertising.

Theories of Product Proliferation

Interest by economists in the phenomenon of multiple products dates back at least to Hotelling's classic paper on the competitive distribution of sellers. His model postulated consumers equally distributed along an axis representing distance between sellers or some qualitative aspect of a product, such as the sweetness of cider. With free entry and price competition, established sellers will produce cider of average sweetness in order to attract as many consumers as possible. If, on the other hand, entry is restricted or if the sellers agree to avoid price competition, then makers will produce ciders differentiated from each other by sweetness. Competition becomes localized in the sense that changes in quality (or price) only affect the demand for adjacent brands. Each producer is, in effect, an oligopolist, with groups of adjacent producers serving segments of the cider market based on differing sweetness preferences of consumers.

Hotelling's spatial-equilibrium model and Lösch's location model have been extended by analogy to incorporate product (nonspatial) differentiation.[3] Like sellers or plants separated in space by physical distance, the proximity or distance of products in product-attribute space is a measure of qualitative differences. Price differences are analogous to transportation costs. Numerous analyses consider various assumptions about potential entrants' expectations. These analyses have shown that when products are differentiated, even the existence of free entry may not suffice to eliminate excess profits (Lovell; Peles; Hay; Stern; Eaton and Lipsey 1975, 1976; Prescott and Visscher).

Scherer (1979) has developed a simple model to explain the criterion used for launching a new consumer product. Whether or not a new product will be marketed depends on the gain in the discounted present value of producers' surplus relative to the fixed costs of introduction (research and development, market research, test marketing, introductory advertising, and additional plant capacity). The size of the potential producers' surplus is in turn affected by the market structure. Under Cournot-like reaction assumptions and free entry, monopolistic competition yields higher surpluses than pure monopoly. Alternative assumptions about entry conditions and oligopolistic reactions yield different potential gains in producers' surplus. The entrant's surplus (transfers from consumers, pure

[2] All the tests of quality differences cited predate the appearance of so-called generic grocery products. Like the second-line, private-label items previously offered by some retailers, generics typically utilize less costly ingredients and packaging. On the other hand, at least one major grocery chain sold their regular first-line private label products with generic labels affixed. Generics are usually priced 25% to 35% less than the leading national brand equivalents.

[3] Two other theoretical approaches also have been used to examine product diversity. Dixit and Stiglitz adopted an orthodox consumer-utility framework to analyze optimal product diversity. Lancaster has studied the same problem using his characteristics-preference model. Ironmonger also used a consumer demand approach to analyze the impact of new commodities on demand elasticities and their life cycles. Though formally similar to spatial equilibrium models, theories of consumer demand have not been useful for introducing market-structure characteristics on the sellers' side.

Chamberlin, Spence, and Scherer (1979) also may be considered a distinct tradition interested in the phenomenon of product diversity. Utilizing the concepts of monopolistic competition and Marshallian consumers' surplus, they have attempted to measure or predict the social welfare impacts of product proliferation. See the final section of this paper.

surplus, and transfers from other producers) varies considerably depending on the substitutability between new and adjacent products.

Schmalensee has constructed a more formal, spatial-equilibrium model to analyze product proliferation in a differentiated food-manufacturing industry. He demonstrated that, if established firms collude to deter entry, then increasing the number of brands of a given product is more (jointly) profitable than "limit pricing," the strategy of limiting entry by lowering prices, thus sacrificing short-run for long-run profits. In an industry characterized by brand proliferation, an equilibrium is possible in which established brands earn excess profits but no potential entrant can profitably enter. He also deduced that brand proliferation deters entry by unbranded (private label) imitators more effectively than does limit pricing.[4] Finally, Schmalensee demonstrated that excess advertising is an effective alternative to brand proliferation for deterring entry. While Schmalensee's results depend on the existence of localized rivalry (brands are immobile in the sense that a repositioning in quality space is too costly for a seller to consider), relaxation of this assumption to finite repositioning costs does not appear to alter his conclusions (Eaton and Lipsey 1975).

Another theoretical approach to product proliferation is "commodity bundling." In a formal model developed by Adams and Yellen, bundling includes products available in different containers, multiple unit packages, and "incarnations of the same product, differing in either real or perceived quality" (p. 475). Their model assumes a monopolist selling either two noncomplementary products with equal unit cost curves or a single product with two separable characteristics. They demonstrate that pricing strategies can be followed to extract consumer surplus by sorting buyers into groups with different reservation prices. Bundling is similar to price discrimination and under some conditions a more profitable strategy. Finally, their normative analysis of commodity bundling concludes that it generally produces nonoptimal product quantities and causes a significant redistribution of income from buyers to sellers.

A less formal analysis of product proliferation is in a recent paper by Koller. He considers product proliferation as one of the three most common forms of predatory conduct, far more prevalent today than classical predatory pricing. Proliferation conforms to the three criteria of successful predation: (*a*) the predator earns quasi-rents, (*b*) the market is restructured, and (*c*) rivals or buyers are made worse off. Consumers may be better off initially because of the availability of new products, but eventually they are worse off because proliferation preempts entry by actual or potential competitors. Koller argues that, because the investment is covert and because the barrier is erected as soon as the product is marketed, proliferation takes rivals by surprise, thereby making it generally more effective than predatory pricing wars. Because of employee turnover, test marketing, and industrial spying, in actual practice secrecy is difficult to maintain, thus blunting the element of surprise.

In sum, economic theory suggests that new grocery product development is primarily a form of nonprice business conduct whose roots lie in market structure. A firm that already holds a leading position in a given market will find it advantageous to develop products in adjacent product-space niches for several reasons. First, adjacent products may appeal to a new set of consumers and offer present consumers additional variety. Developing products in adjacent positions may also be an effective defensive strategy to maintain market share for a firm's leading items (Friedman). Second, the firm eventually may be able to offer a full line of products. A full line allows a brand name to be more fully exploited, may justify employing a field sales force, or may confer some pecuniary economies of scale in advertising and promotion. Third, product proliferation of this kind generally will require the allocation of substantial retail store shelf space. In order to duplicate or imitate the line, a new entrant would require a similarly large allocation of shelf space by retailers. Because this is unlikely for all but the most powerful of manufacturers, product proliferation is a barrier forestalling entry at the retail level. Fourth, being the first or second in

[4] In a personal communication Schmalensee notes that in the breakfast cereal industry, some private-label manufacturers find entry foreclosed because the brand has achieved a nearly generic identification; in these cases, attempting to identify the contents of a box of an imitative breakfast cereal might constitute trademark infringement. A related device is "trademark banking." This practice consists of registering numerous variants of successful or potentially useful brand names far in advance of actual introduction; most are never used. One major food manufacturer has over 1,300 trademarks registered in the United States.

a market has been shown to confer future high market shares (see, for example, Whitten).

Measuring Product Proliferation

The concept of a "new" food product varies widely from writer to writer. Some claim that there are no truly new foods, while others estimate that several thousand new foods appear each year The problem of definition depends partly on the point of view of the agent in the food system; as Buzzell and Nourse have argued, manufacturers, retailers, and consumers each have differing perceptions of newness.

Buzzell and Nourse proposed that new products can be classified according to their degree of novelty. This paper will follow their lead. First, the rarest and most innovative product introductions will be termed distinctly new products, types, or categories. Second, a more common kind of product proliferation is brand proliferation (imitations of successful new types by other producers) or line extensions (by the introducing firms). Finally, the most frequent type of proliferation will be called item proliferation, repositioning, or reformulation. These distinctions also fit within a time framework. That is, first, a new category is created; second, brand proliferation or line extensions occur; third, item proliferation and repositioning are observed.

Connor (1980a) reviewed four secondary data sources on new grocery product introductions. Two sources detailed their selection of distinctly new food products. Buzzell and Nourse identified only 22 such products in the 1945–65 period. The editors of *Progressive Grocer,* on the other hand, selected about 25 food products introduced in the late 1970s as especially innovative. *New Product News,* a trade magazine, found that on average nearly 900 new brands of packaged consumer goods were being introduced yearly during 1964–70; item proliferation (excluding package sizes), however, was considerably greater, averaging over 1,950 per year. In both cases, product proliferation showed a steady upward trend after 1973. More than half of all food and beverage proliferation in 1977 was accounted for by frozen foods, candy, beverages, and snack items.

Grocery warehouse withdrawal records are a fourth source of new product introductions. Though these records do not count nonwarehoused or direct-store-delivery items (e.g , produce, perishable dairy items, and fresh bakery products), they provide a very complete and most cited accounting of new branded grocery products. For example, the Nielsen Early Intelligence System (NEIS) found that an average of more than 6,000 items entered national distribution per year during 1973–78. More than 5,000 per year were edible products. The NEIS data indicate a much larger number of new item introductions than *New Product News* because the former includes even trivial package size changes or additions. Because some existing items must be dropped to make room for the new, the average net increase of grocery items in U.S. wholesale distribution was about 4.7% per year in the 1973–78 period.

A final data source on product proliferation is a report of "significant" new consumer packaged products compiled monthly for many years by the staff of *Advertising Age* magazine. Because these data provide information on individually identified new products, they form the basis for the statistical analysis in the next section. In particular, it was possible to classify each product by its five-digit SIC number (the Standard Industrial Classification system divides manufactured foods into 130 five-digit product classes), determine the parent company for each brand, and eliminate the mere "repositioning" (change in advertising appeal or theme) or "reformulation" of products. New flavor varieties were counted, but new sizes and redesigned packaging were ignored. Regional and national offerings of new products were counted, as were full test-marketings. Thus, these *Advertising Age* data include brand proliferations or line extensions but not mere item proliferations.

Five categories account for over 50% of the introductions (table 1); about 53% of 732 new products recorded were processed food or beverage products. The high proliferation categories are generally characterized by high concentration, high advertising intensities, and other oligopolistic market features (Connor 1980c; canned items were predominantly canned ethnic specialties; the frozen foods, mainly frozen pizza and entrees). There was a relatively low rate of brand proliferation in two nearly monopolized industries, baby foods and canned soups.

Most product proliferation can be attributed to firms already established in food process-

Table 1. New Packaged Consumer Food and Tobacco Products Introduced by Product Category, 1977–78

Product Categories	New Products Introduced[a] 1977	1978
Nonalcoholic beverages and mixes	32	38
Alcoholic beverages	21	28
Pet foods	20	19
Flour mixes and baking ingredients	18	10
Frozen foods	18	12
Tobacco products	16	7
Canned fruits, vegetables, and specials	14	12
Candy and chewing gum	11	16
Breakfast cereals	10	14
Meat and fish	10	1
Bread, cakes, crackers, and cookies	9	11
Dehydrated vegetables and soup mixes	9	6
Dairy products	7	4
Chips	5	11
Margarine and oils	3	4
Prepared desserts	3	0
Baby foods	2	0
Canned soups	1	0
Sauces and dressings	1	0
Total	210	209

[a] A simple count of all new brands, flavors, and line extensions. Minor changes in packaging, different package sizes, reformulations, and repositionings were not counted.

ing. Of the 419 new food and beverage products introduced during 1977–78, 59% were introduced by the 50 largest food or tobacco processing firms, and 70% originated from among the 200 largest. Only 11% of the products were marketed by firms with no recent products in the category. Because *Advertising Age* depends to some extent on announcements distributed by the firms themselves, these data may be biased toward larger firms. However, they are consistent with the *New Product News* data for 1977, which shows that only 15 large firms account for nearly 20% of all products.

The Model

The model tested here is a simple, linear equation which assumes that market structure elements (and control variables) impact additively on brand proliferation. The dependent variable is a simple count of the total 419 new branded food manufactures introduced into each of 102 product classes during 1977–78 (see appendix table 1 of Connor 1980a). Because the dependent variable takes on only a limited number of integral values, it has a multinomial distribution and the estimated coefficients and t-tests only approximate the true values (Kmenta, pp. 425–27).

The independent market-structure variables refer to 1972–75 data.[5] To model the potential for cooperation among established sellers, the four-firm sales percentage concentration ratio (*CR*4) is utilized. The square of four-firm concentration (*CR*4*SQ*) was added on the expectation that tight oligopolies (canned soup, infant foods, etc.) may have densely packaged product-attribute spaces. This discourages a high rate of product proliferation because existing, adjacent variants are close substitutes for contemplated new variants. The extent of product differentiation is captured by the percentage eight-media advertising-to-sales ratio of the top four firms in each product class (*ADS*). The estimated coefficient of *ADS* may be biased upward because of the heavy introductory media advertising associated with many new products. The final structural variable is the percentage of direct production costs incurred by the census industry for packaging materials (*PACKCOST*). Just as media advertising intensity is expected to capture the extent of differentiation in the psychic attributes of food products, heavy packaging costs may be a proxy for the ease with which food products can be physically differentiated from one another. Also, packaging may serve to reinforce media advertising messages.

Control variables also are introduced into the model. The natural logarithm of the 1975 wholesale shipments value of each product class (*SIZE*) is a proxy for the density of potential demand for new products. All else held constant, a large product class is likely to have a larger number of exploitable demand segments than a small product class. The percentage change in product class shipments value during 1967–72 (*GROW*) is designed to reflect shifts in demand and tastes which likely encourage product proliferation. On the other

[5] These data were originally developed for Parker and Connor. Appendix D of their working paper contains definitions, sources, and a complete listing of the values of the independent variables for all 102 consumer product classes in the food-manufacturing industry. Following census practice, ten product classes (e.g., 20116 and 20136) were combined into five observations.

hand, past high growth rates may identify product classes with high proliferation in the past and densely packed classes in the present. Thus, *GROW* could be negatively related to the short-run rates of proliferation being explained in the present model. The final control variable is *PLSHR*, the percentage of the product class' sales in private-label products in 1976 (if unreported, it was assumed to be zero). Because *Advertising Age* compiled data on new branded products only, the larger the private-label segment of the market, the less likely are new products to be introduced into the branded segment. In a sense, *PLSHR* is a correction for *SIZE*.

The independent variables *CR4*, *ADS*, *PACKCOST*, and *SIZE* are expected to exhibit positive regression coefficients; *PLSHR* and *CR4SQ* should be negative; and *GROW*'s effect is ambiguous. The units of observation are the 102 consumer products classes in food manufacturing (*SIC* 20).

The Results

The OLS regressions are displayed in table 2. The simplest equation (2.1), explains only 23% of the variance in levels of product proliferation. Both structural variables have the correct signs; advertising intensity is significant at the 1% level; and *CR4* is significant at the 5% level. The inclusion of *SIZE* in equation (2.2) and all succeeding equations markedly improves the goodness of fit; it is highly significant and positive as expected. A parabolic specification is used for seller concentration in equations (2.3) through (2.7). The second-degree term *CR4SQ* is significant, the critical point being reached between the 60% and 70% concentration levels. In equation (2.4) *PACKCOST* is significant and displays the expected positive relationship with product proliferation. The reduction in the size of the coefficient on *ADS* indicates that media-generated and physical differentiation are to some extent substitutes in food industries. Long-run past growth has no significant influence on new product introductions, equation (2.5), but the share of the market going to private-label sales has a weak negative impact as expected, equation (2.6). The final equation combines all six factors. Overall, equation (2.4) appears to be the best-fitting model, with four factors explaining nearly half of the variance in brand proliferation among processed foods. An examination of the residuals found no evidence of heteroskedasticity, nor did multicollinearity appear to be a problem.

The regression analysis indicated that prod-

uct proliferation was unrelated to industry growth. Several other factors were tested and found to be insignificant. Three variables representing barriers to entry were developed: the ease of foreign entry as represented by high U.S. imports and two economies-of-scale barriers to entry. Three variables representing industry progressiveness also were tested. One, the ratio of research and development expenditures to sales, is a measure of innovative effort. Two others attempted to capture technological progressiveness on the output side: the number of U.S. patents assigned to food companies (principally classified in the industry) during 1961–75 and the number of scientific and technical publications by food company employees during 1965–75. However, neither economies of scale nor technological progressiveness were significantly related to food product proliferation. The latter finding is rather surprising, because many writers have inferred that inventiveness would lead to innovativeness as revealed by new product marketings. However, it is possible that food-manufacturing inventiveness effects improvements our data do not measure. Alternatively, progressiveness in other industries, for example the packaging industry, may improve the quality or increase the quantity of food products.

The empirical results confirm that imperfect market structures do indeed generate high levels of food product proliferation. There is a significant relationship between brand proliferation and the concentration of sales and advertising intensity. With an industry structure regarded as workably competitive ($CR4 = 40$, $ADS = 1$), equation (2.4), holding *SIZE* and *PACKCOST* at their means, predicts about 1.5 new products per year per product class. Higher levels of concentration and advertising, say $CR4 = 60$ and $ADS = 10$, imply the introduction of 11.5 new food brands per year per product class.

The results reported here for the food-manufacturing industries provide empirical support for the market structure-conduct linkage suggested by Schmalensee's model. Product proliferation is one of several forms of business conduct open to firms in oligopolistic industries with differentiated products, but it appears to be a widespread strategy in the food industries. This paper has not dealt directly with the normative or performance impacts of food product proliferation, but they are likely to be profound.

Normative Implications

Theoretical treatments of the welfare effects of product variety are inconclusive. The existence of a trade-off between the increased satisfaction that consumers derive from being able to match their tastes more precisely to market offerings and the decreased welfare effects of higher product prices has long been recognized (Chamberlin 1933). More recent formal welfare analyses of optimal product diversity have arrived at no clear judgment on the net effects (Lancaster; Dixit and Stiglitz; Stern; Spence). Schmalensee likewise argues that there are not necessarily too many products for a given market even though product proliferation deters entry. However, his analysis suggests that in such markets some reduction in prices, holding the product mix constant, would trivially increase net welfare.

There are two studies that have attempted to assess the social value of food product proliferation. Nyström and Edvardsson attempted to measure the producer and consumer benefits of all 121 new food products introduced during 1969–78 by the twenty Swedish food-processing companies most active in research and development. Their performance standards (technological novelty, taste quality, convenience, nutritional value, price relative to closest existing substitute, and profitability) were largely judgmental. From the point of view of consumers, about one-third of the new products were ranked superior and one-half the same as existing close substitutes.

More formal estimates of the welfare benefits of product proliferation are given in a recent paper by Scherer (1979) on the ready-to-eat cereal industry. He estimated the fixed costs of introduction, producers' surplus gains, and consumers' surplus gains for seventy-six ready-to-eat cereal brands introduced during 1958–70. The average minimum fixed costs were $4.4 million per brand (1962 dollars). By the mid-1960s industry growth had become flat; as a result consumers' surplus declined and new product introductions increasingly involved only interproducer transfers ("cannibalization"). Both the prices and profit margins for new ready-to-eat cereals averaged about 30% higher than existing brands, which led to substantial transfers from consumers' to producers' surplus. Nevertheless, consumers' surplus averaged about 20% of wholesale prices. By his calculations, about

22% to 30% of the brands introduced (33% to 43% of those introduced beyond the regional-test stage) generated positive net social benefits. In sum, "it appears probable that product proliferation has, at least at the margin, cost more than it was worth" (Scherer 1979, p. 133).

Taken together, these studies suggest that product variety in mature, highly oligopolistic food industries may be excessive. Henning and Mann (p. 262) strongly advocate public policies limiting product proliferation, primarily because they consider it a major cause of excess advertising. Padberg and Westgren opined that traditional antitrust remedies are unable to deal with the performance impacts of product proliferation. I am aware of only one piece of U.S. legislation that was prompted by a concern about proliferation; the Fair Packaging and Labelling Act of 1966 directed the Department of Commerce to reduce the proliferation of packaging sizes via voluntary industry agreements.

The belief that product proliferation is an anticompetitive practice was an important element in the decision of the Federal Trade Commission to bring its eight-year-old antitrust case against the major ready-to-eat cereal companies. Because no economic norm of optimal product diversity has yet been developed, and because measurements of product proliferation are subjective or arbitrary, the direct regulation of industry performance or structural improvements may be public policy approaches superior to policies tailored specifically to optimize rates of product proliferation.

A Sector Analysis of Alternative Income Support and Soil Conservation Policies

W. G. Boggess and E. O. Heady

For nearly five decades Congress has attempted to legislate both higher farm incomes and soil conservation. A national, interregional, demand-endogenous, separable programming model is used to analyze the potential of alternative policies to achieve simultaneously the dual goals of increased farm income and reduced soil erosion. The analysis indicates that a conservation-oriented land retirement policy can be designed to achieve an increase in net farm income equivalent to a traditional general land retirement policy, while simultaneously achieving significant reductions in gross soil erosion, chemical input use, and direct government program costs.

Key words: endogenous demands, income support, interregional analysis, separable programming, soil conservation.

The United States has a long history of government intervention in agriculture. Efforts to legislate soil conservation began with the Soil Conservation and Domestic Allotment Act of 1936 and continue today. This study assesses the potential of alternative policies to achieve simultaneously the dual goals of increased farm income and reduced soil erosion.

Following the method outlined by Duloy and Norton, a national interregional separable programming model of the U.S. agricultural sector is formulated. Four alternative combinations of supply control and soil conservation policies are analyzed to ascertain their impact on regional farm prices and incomes, farm output, farm input use, and gross soil erosion.

Model Specification

Previous agricultural policy models have included both mathematical programming models (Taylor and Frohberg, Stoecker, and Meister et al.) and simulation models (Tyner and Tweeten, Ray and Heady, and Ray and Richardson). Mathematical programming models provide normative answers to problems. Normative courses of action are those which ought to be taken by the agricultural sector, given (*a*) the particular objective function specified and (*b*) the conditions and restraints surrounding the alternatives available (Heady and Candler). In contrast, a positive analysis predicts how farmers would actually respond to a particular policy. Both types are needed.

A mathematical programming model is used here because it can help analyze policies in which the underlying structural framework changes. Furthermore, it provides the regional detail necessary for analyzing the interregional impacts of the alternative policies. (McCarl and Spreen present an excellent discussion of the usefulness and limitations of mathematical programming for policy analysis at the sector level.)

The model provides comparative static rather than dynamic analysis. The optimum plan, after implementation of a policy or structural change, is compared to the optimum plan before implementation of the policy or structural change. This comparison shows the impact of the change on the response variables. It does not, however, provide information on the dynamics of moving from the old to the new optimum plan.

A mathematical programming problem consists of a simultaneous equation network rep-

William G. Boggess is an assistant professor of food and resource economics at the University of Florida. Earl O. Heady is distinguished professor of economics and Director of the Center for Agricultural and Rural Development at Iowa State University.

The authors express their appreciation to the anonymous *Journal* reviewers for their helpful comments on earlier versions of this paper.

resenting the constraints on the system plus an additional equation to represent an optimized functional relationship. A mathematical description of the model follows.

Objective Function

The objective function maximizes the area between the demand and supply curves. Linear demand functions for beef, pork, milk, wheat, oils, and feed grains are of the form,

$$\mathbf{P} = \mathbf{A} + \mathbf{BQ}, \tag{1}$$

where **P** is the price vector, **A** is the intercept vector, **B** is the matrix of slope coefficients, and **Q** is the vector of quantities. They are estimated and incorporated into the model structure. The intercept and slope coefficients were obtained from an updated version of Stoecker's quadratic programming model using 1985 projected populations and incomes.

Following Duloy and Norton, grid linearization (separable programming) techniques are used to incorporate the interdependent demand functions endogenously in a linear programming context. Given the demand relationships in equation (1), Duloy and Norton formulated an objective function which maximizes the area between the demand and supply curves represented mathematically[1] as

$$\text{(2)}\quad \text{maximize } Z = \int_0^{q_n} \cdots \int_0^{q_1} (A + BQ)\, dQ - C(Q) = Q'A + .5\, Q'BQ - C(Q),$$

where $C(Q)$ represents the supply side of the market. The model treats input prices as fixed. Implicitly, this is equivalent to assuming that the supply functions for inputs are perfectly elastic. In reality, changes in sector-wide demands for inputs could have significant impacts on input prices and thus production costs and farm income. As output expands, the demand for, and thus the price of, inputs normally will rise unless the input supply functions are perfectly elastic. Allowing input prices to rise in response to an increase in demand will result in proportionately greater increases in production costs and a proportionately smaller increase in net returns than are suggested by this model. The rising input prices also would tend to dampen the output response relative to that exhibited by this model. If input supply elasticities are available, the separable programming framework can be modified to incorporate endogenously the price effects of changing demands for inputs following the approach outlined by Hazell.[2]

Equation (2) is quadratic in Q. Expansion of the term $.5Q'\ BQ$ results in squared and cross-product terms. The cross-product terms are not separable, and a transformation is required to obtain separable functions. The separable variables in equation (2) were modelled using the IBM MPSX separable programming routine.

The overall objective function incorporating both the separable demand and the supply sides of the markets may be expressed mathematically as

$$\text{(3)}\quad \max.\ Z = \sum_n \sum_s A_{ns}Q_{ns} + \sum_n \sum_s \sum_r \sum_v B_{nsrv}SV_{nsrv} - \sum_i \sum_j \sum_k \sum_m X_{ijkm}XC_{ijkm} + \sum_n \sum_s \sum_q L_{nsq}LC_{nsq} - \sum_i W_i WC_i - \sum_i IB_i IC_i - \sum_n \sum_s \sum_t T_{nst}TC_{nst}.$$

A definition of these terms and subscripts follows the mathematical expression of the constraints.

Model Constraints

Constraints on the model include acreage of dry and irrigated land available for production of the endogenous crops, acre-feet of water available for use by endogenous crops and livestock, commodity balance rows, a national cotton demand equation, and the grid and constraint rows associated with the separable programming formulation of the demand equations. Mathematical expressions for each follow.

Dryland acreage by land class by producing area:

$$\sum_k \sum_m X_{ijkm}AD_{ijkm} \le DA_{ij}. \tag{4}$$

[1] Integration of (2) is possible only if B is symmetric. McCarl and Spreen discuss this requirement and suggest ways of relaxing this assumption.

[2] McCarl and Tice discuss the use of matrix diagonalization as a solution to this problem.

Irrigated land acreage by land class by producing area:

$$(5)\qquad \sum_k \sum_m X_{ijkm} AI_{ijkm} \le IA_{ij}.$$

Water availability by producing area:

$$(6)\quad \sum_j \sum_k \sum_m \sum_u X_{ijkm} W_{ijkmu} CWU_{iu} + \sum_n \sum_p \sum_q L_{nq} LWU_{nsq} LW_{ni} \le WS_i.$$

Endogenous crop commodity balance rows by demand region:

$$(7)\quad \sum_i \sum_j \sum_k \sum_m X_{ijkm}\, W_{ijkmu}\, CY_{ijkmsu} - Q_{ns} - \sum_t T_{nst} \ge CD_{ns}.$$

Endogenous livestock commodity balance rows by demand region:

$$(8)\qquad \sum_q LY_{nsq}\, L_{nsq} - Q_{ns} \ge LD_{ns}.$$

Cotton demand at the national level:

$$(9)\quad \sum_i \sum_j \sum_k \sum_m X_{ijkm}\, W_{ijkmu}\, CY_{ijkmu} \ge DC.$$

Subscripts in equations (3) through (9) refer to the following:

$n = 1, \ldots, 8$	for the demand regions;
$s = 1, \ldots, 6$	for the endogenous commodities;
$r = 1, \ldots, 6$	for the endogenous commodities;
$v = 1, \ldots, 10$	for the number of steps defined for each separable variable;
$i = 1, \ldots, 105$	for the producing areas;
$j = 1, \ldots, 10$	for the land quality classes;
$k = 1, \ldots, 330$	for the crop rotations;
$m = 1, \ldots, 12$	for the alternative conservation and tillage practices per rotation;
$q = 1, \ldots, 32$	for the livestock rations;
$t = 1, \ldots, 76$	for the transportation routes defined; and
$u = 1, \ldots, 10$	for the possible irrigated crops.

Variables in equations (3) through (9) are defined as follows:

A_{ns} is the linear demand coefficient for commodity s in region n;

Q_{ns} is the number of units of commodity s marketed in demand region n;

SV_{nsrv} is the separable variable step v, defined for each squared ($s = r$) and cross-product ($s \neq r$) term for commodities marketed in region n;

B_{nsrv} is the demand coefficient corresponding to step v of each of the squared and cross-product terms for commodities marketed in region n;

X_{ijkm} is the level of rotation k using conservation-tillage method m on land class j in producing area i;

XC_{ijkm} is the cost per acre of rotation k with conservation-tillage practice m in producing area i on land class j;

L_{nsq} is the number of units of livestock activity s receiving ration q in demand region n;

LC_{nsq} is the cost per unit of livestock activity s receiving ration q in demand region n;

W_i is the number of acre-feet of water purchased in producing area i;

WC_i is the cost per acre foot of water purchased in producing area i;

IB_i is the acre-feet of water transferred out of producing area i;

IC_i is the cost differential on a per acre foot basis for water in producing area i;

T_{nst} is the number of units of commodity s transported over route t from demand region n;

TC_{nst} is the cost per unit of commodity s transported over route t from demand region n;

AD_{ijkm} is the acres of dryland used per unit of rotation k using conservation-tillage method m on land class j in producing area i;

DA_{ij} is the acres of dryland available for endogenous crops on land class j in producing area i;

AI_{ijkm} is the acres of irrigated land used per unit of rotation k using conservation-tillage method m on land class j in producing area i;

IA_{ij} is the acres of irrigated land available on land class j in producing area i;

W_{ijkmu} is the rotation weight for crop u in rotation k using conservation-tillage method m on land class j in producing area i;

CWU_{iu} is the acre feet per acre water use coefficient for crop u in producing area i;

LWU_{nsq} is the acre feet per unit water use coefficient for livestock type s consuming ration q in market region n;

LW_{nsi} is the proportion of livestock type s from demand region n falling in producing area i;

WS_i is the acre feet of water available for use by the endogenous agricultural sector in producing area i;

CY_{ijkmsu} is the per acre production of commodity s from crop u in rotation k using conservation-tillage system m on land class j in producing area i;

CD_{ns} is the exogenously determined demand for commodity s in demand region n;

LY_{nsq} is the yield of commodity s from livestock activity q in demand region n;

LD_{ns} is the exogenously determined demand for livestock commodity s in demand region n;

CY_{ijkmu} is the per acre production of cotton in rotation k using conservation-tillage practice m on land class j in producing area i; and

DC is the exogenous national demand for cotton.

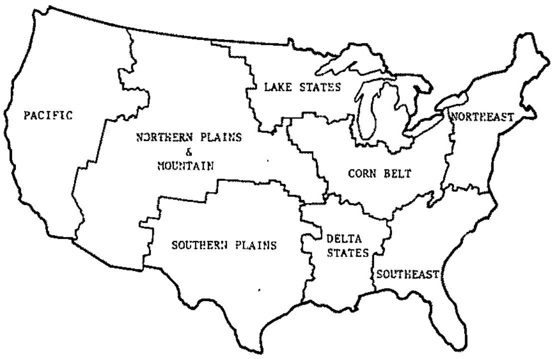

Figure 1. The eight demand regions

Regional Delineations

In order to represent the interregional competitive aspects of U.S. agriculture, the major constraints and demands on the agricultural production sector are formulated regionally. Three sets of regions are defined in the model: the crop production regions, the livestock production and market regions, and the endogenous demand regions.

Crop production activities and the land base are defined for 105 producing areas. The producing areas are derived from the Water Resource Council's 99 aggregated subareas (U.S. Water Resources Council). Water resources are defined for the producing areas corresponding to the 17 Great Plains, Mountain, Southwest, and Pacific states. Livestock production activities and the exogenous commodity demands and exports are defined for 28 market regions. The market regions are aggregations of contiguous producing areas.

The eight endogenous demand regions of figure 1 are aggregations of contiguous market regions. Each demand region is the demand and transportation center for the endogenous commodities. Metropolitan centers in each region form the model's transportation sector.

Major Sectors of the Model

A brief description of each of the major components of the model follows. Additional information about the model specification and formulation is available from the authors.

Demand Sector

The demand sector consists of three categories: (*a*) demands for endogenous commodities for which equations are specified, (*b*) fixed demand for the endogenous crop, cotton, and (*c*) demands for exogenous commodities. Each of the three demand categories incorporates net export, domestic consumption, and intermediate uses.

The fixed demands for cotton, the exogenous crops, and projected net exports are 1985 government projections (Quance, Smith, Powell). Adjustments were made in the model's resource base for the quantities of land, water, nitrogen, and feedstuffs either utilized or produced by the exogenous crops.

Land Base

The cropland base is derived from the Conservation Needs Inventory (CNI), which reports acres of land by use and agricultural capability class (Conservation Needs Inventory Committee). The CNI county acreages are aggregated for dryland and irrigated uses into the 105 producing areas and into 5 quality classes. The 5 quality classes are aggregations of the 29 CNI agricultural capability classes and subclasses. The CNI capability class and subclass distinctions are based on the relative suitability of the land for agricultural production purposes. The projected 1985 land base is derived from the original CNI by adjusting for projected wetland drainage, irrigation development, and conversions to urban and other nonagricultural uses by 1985 (Meister and Nicol).

Crop Production Sector

The crop sector contains barley, corn, corn silage, cotton, legume hay, nonlegume hay, oats, sorghum, sorghum silage, soybeans, and

wheat. Unique production activities are defined for each of five land quality classes in each of the 105 producing areas. Each crop management activity consists of a rotation, a tillage and conservation practice, and irrigated or dryland farming utilizing the nitrogen, land, and water resources available. Crop production costs include machinery, labor, pesticide, and miscellaneous costs. These costs were developed using the U.S. Department of Agriculture's (USDA) Firm Enterprise Data System (FEDS) crop budget generator.

Gross soil loss as calculated in the model represents the average annual tons of soil leaving the field. This measurement of soil loss does not represent the amount reaching streams or bodies of water. Two separate procedures were used to determine gross soil loss per acre. For the areas east of the Rocky Mountains, the "Universal Soil Loss Equation" was used (Wischmeier and Smith). For areas west of the Rocky Mountains, soil loss coefficients for each management system were derived from a Soil Conservation Service questionnaire.

Livestock Sector

The livestock sector consists of beef cows, feeders, dairy, and hogs. Several alternative rations, reflecting optimum input ratios for alternative output levels and price ratios are specified for each type of livestock. Activity costs include all production costs except feed, which is endogenously determined. Nitrogen in livestock manure is a source of fertilizer to the crop sector (Short and Dvoskin).

Water Sector

The water sector defines water supplies in the western United States. Dependable supplies of both surface and ground water are defined (Colette). Water prices are acreage-weighted, average reimbursable costs of the Bureau of Reclamation water projects. Water transportation activities are defined reflecting both natural and manmade flows.

Transportation Sector

Interregional interdependence is introduced through the transportation sector. Transportation routes are defined between all contiguous regions. Transportation costs are based on 1975 rail rates for grains and truck rates for livestock commodities using the mileage between the metropolitan centers of the demand regions.

Policy Alternatives

Four alternative combinations of supply control and soil conservation policies are analyzed to test their impact on regional farm prices and incomes, farm output, farm input use, and gross soil erosion. The four policy alternatives consist of a baseline (Alternative A); a maximum allowable per acre soil loss equal to the soil tolerance levels (Alternative B); a 10% land retirement, supply control policy designed without special conservation aspects (Alternative C); and a 40% land retirement policy designed as a simultaneous supply control mechanism and soil conservation program (Alternative D).

Alternative A is based on a projection to 1985 of baseline demands and export levels in the absence of land retirement or soil loss policies. Alternative B represents a soil conservation policy apart from supply control or land retirement. Under Alternative B, crop production activities whose estimated per acre gross soil losses exceed the established soil tolerance levels are restricted from entering the solution. The soil loss tolerance levels reflect the maximum yearly allowable soil loss consistent with maintaining economically indefinite productive capacity of the soil (Wischmeier and Smith). Soil tolerance levels range from one to five tons per acre per year depending upon soil properties, topography, and prior erosion.

Alternatives C and D represent two alternative land retirement or supply control policies. Alternative C assumes that 10% of all endogenous cropland is retired from production. The 10% reduction is distributed evenly across all land classes and regions. Hence, all farmers and regions would be treated similarly with respect to land retirement. Alternative D assumes that 40% of the cropland in the Conservation Needs Inventory quality classes, III_e, IV_e, VI, VII, and VIII is retired from production. Alternative D thus incorporates components of both supply control and soil conservation into a single policy concentrating land retirement in regions or locations where land is most erosive.

Results

This programming model is designed for normative planning and impact analysis rather than positive prediction. As such, comparisons between alternative solutions of the model can be more valid and useful than comparisons with current actual values. However, it is informative to compare the baseline model results with current values in order to provide some indication of the "realism" of the basic model structure.

Alternative A is a normative benchmark for comparisons with the policy alternatives. It reflects baseline projections of moderate or trend level estimates of population, per capita consumption, and exports. In addition, agriculture is assumed to operate under perfectly competitive conditions without explicit policies designed to increase farm income or reduce soil erosion.

Table 1 presents a regional comparison of some of the model's key baseline results with 1977 actual values. The regional distribution of crop acres in the baseline model closely approximates the 1977 actual distribution. The largest variation in acreage is only 1.2% in the Corn Belt. With the exception of the Delta States, the baseline model consistently overstates per acre soil losses relative to the 1977 Erosion Inventory estimates. The primary reason is that the model chooses the profit-maximizing combinations of rotation, conservation practice, and tillage practice, but, in reality, some erosive land already has been terraced and many farmers follow sound conservation practices as a matter of principle. The regional income comparisons exhibit the most variation and are the least reliable of the three data items. Nationally, the baseline estimate of net farm income is nearly identical to the 1977 actual figure. However, the model structure does not allow estimation of regional net farm income. Instead, only net farm returns from endogenous crops are available regionally.

Policy alternatives B, C, and D each reflect a different approach toward the dual goals of increasing farm income and conserving soil. Alternative B was formulated with the singular policy objective of conserving soil, Alternative C with the sole policy objective of increasing farm income, and Alternative D with the dual objectives of increasing farm income and con-

[g] Estimated total U.S. net farm income in the baseline model is $29,206 million.

serving soil. Consequently, the alternatives have quite different impacts on the degree of soil conservation and the increased income generated.

With Alternative B, the soil loss limit results in a 68% decline in both total and per acre gross soil erosion arising from endogenous crop production relative to A (table 2). Table 2 also indicates that both total and per acre erosion losses are reduced substantially in all regions. This result is precisely what should be expected from such a policy. However, a second less obvious result of the soil loss policy is that net farm income increases by 8% relative to the baseline (table 3). The increased income results from the decline in output when soil loss restrictions are imposed, coupled with the inelastic commodity demands.

Regional net farm returns from the endogenous crops are reported in table 4. The soil conservation policy, Alternative B, has the least impact of any of the alternatives analyzed. With the exception of the Northeast, no region's share of net returns from the endogenous crops varies by more than 2% of the base. A shifting of endogenous crops out of the Northeast region, coupled with the increased cost of production incurred in response to the soil loss restrictions, results in the relatively large decline in endogenous net returns in the Northeast.

The reductions in gross soil loss with Alternative B were achieved by reducing the row crop intensity, increasing the use of conservation practices (contouring, strip cropping, and terracing), and increasing reduced tillage prac-

tices. However, the reductions in gross soil loss were achieved by increasing total and per acre use of chemical pesticides and fertilizers, table 5. As a result of this substitution of chemical for mechanical inputs, part of the environmental improvements associated with less soil erosion may be offset.

Under Alternative C, 37 million acres, or 10% of the endogenous cropland, is retired from production (table 6). This figure was selected so that endogenous prices increased to a level approximating 1979 target prices. As a result, net farm income increased 15% over the base level. This increase was the sole objective of Alternative C. Alternative D, on the other hand, was designed to achieve a net farm income increase equivalent to that obtained under C, while simultaneously trying to reduce gross soil erosion as much as possible through the sole use of land retirement. The objectives of Alternative D were achieved by retiring 45 million acres of the most erosive cropland (table 6). Because the land retired under D is less productive than under C, both per acre and total set-aside payments are significantly lower in D (table 6).

Regionally, Alternative C and D have quite similar effects on the distribution of net farm returns (table 4). Regional shares increase in the Southeast, Corn Belt, and Delta States regions and decline in the Northeast, Lake States, Southern Plains, and Pacific regions under both C and D. The largest increase occurs in the Corn Belt, where the share of national net farm returns increases by over 12% in Alternatives C and D relative to A. The largest decline occurs in the Southern Plains, where that region's share of returns declines by over 10% in both C and D relative to A.

The retirement of 45 million acres of erosive lands under Alternative D not only achieved the specified 15% increase in net farm income, but also resulted in 16% less gross soil loss compared to the base (table 2). This reduction

[a] Total payments equal acres retired multiplied by the per acre payments.
[b] Per acre payments equal the average of the land shadow prices in the baseline and corresponding set-aside alternative.

in erosion is less than might be expected for two reasons. First, much of the land formally retired in Alternative D was already essentially idle in the base line model. Second, increased production intensity causes greater per acre soil losses on the land remaining in production. Alternative C, on the other hand, had little impact on either total or per acre erosion nationally.

Both land retirement policies had substantial impacts on regional soil losses. Under C, significant reductions in total soil losses in the Northeast, Southeast, Southern Plains, and Pacific regions were offset by equally significant increases in soil losses in the Lake States, Corn Belt, Delta States, and North Plains regions (table 2). Under D, soil loss reductions were larger and occurred more consistently than under C. The only significant exception was the Delta States region, which experiences a 12% increase in total soil erosion in D relative to the base.

The larger income generated in Alternative C and D results from increased prices associated with a shift in aggregate product supply functions. The actual decreases in production in C and D compared to A are relatively moderate for two reasons. The first is the inelastic nature of the demand for agricultural commodities The second is that purchased inputs (labor, chemicals, and machinery) substitute for the land input in the production process. For example, total purchased input use in C and D increases approximately 4% and per acre use nearly 9% (table 5) relative to A. The largest increases occur in chemical inputs (pesticides and fertilizers). Alternative D not only results in significantly less soil erosion than Alternative C but also in significantly less use of chemical inputs.

The distribution of the burden (cost) of policies designed to increase farm income and conserve soil varies. In each of the three alternatives analyzed, a substantial portion of the burden (cost) is shifted onto consumers in higher prices. However, as usual, part is borne by producers, and this varies by region and producer type.

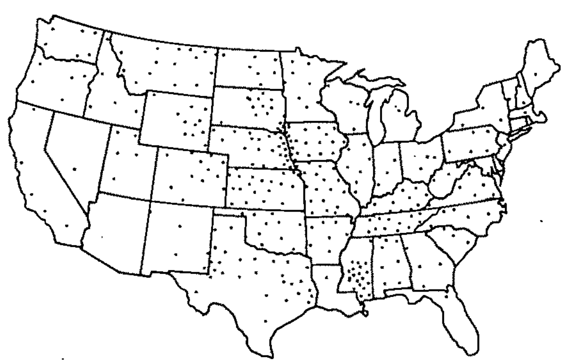
In Alternative B, the soil conservation alternative, producers are forced to limit gross soil erosion to a maximum related to the soil tolerance level. The soil tolerance level is a function of the depth of the topsoil, its productivity, and rate of new soil generation. The estimated rates of soil erosion are a function of topography, rainfall, soil type, and farming practices. Because the rate of new soil generation is relatively constant from one region to the next, and because the thinner the layer of topsoil the lower the soil tolerance level, some regions are affected much more by the soil loss restriction of Alternative B than others. Erosive areas not only display greater erosion rates but also tend to have lower soil tolerance limits because of prior erosion. Thus, meeting the soil tolerance limit in more erosive areas may require substantial adjustments in crops grown, tillage practices employed, and conservation practices used. In other, less erosive areas little, if any, adjustments are required to reduce losses below tolerance levels. Thus, the burden of Alternative B is borne most heavily by producers in the more erosive areas of the nation. The location of land idled under

the soil tolerance level soil loss limits is illustrated in figure 2.

The burden of the 10% homogenous land retirement policy (Alternative C) nationally is distributed more evenly than under B. In C, cropland is retired homogenously across all quality classes and regions; thus, all producers and all regions are affected equally on a percentage basis. In contrast to C, the burden of the 40% conservation land retirement is concentrated exclusively on producers and regions with less productive and more erosive lands (figure 3).

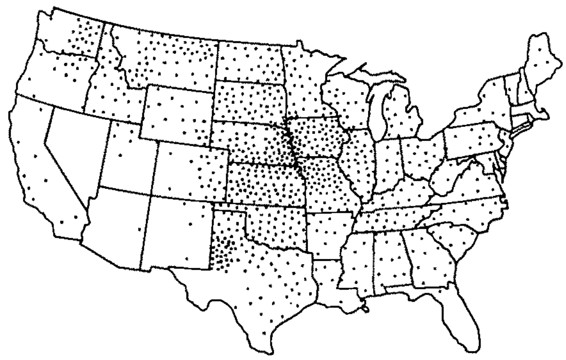
Other Considerations

Retirement of cropland and adjustments in conservation and tillage practices affect the labor and capital requirements of producers. As cropland is retired, the land-labor-capital ratios are significantly changed. Theoretically, if the land-labor-capital ratio was optimal prior to the land retirement and input prices remain constant, labor and capital should transfer out of erosive areas in response to the reduction in land input. However, restrictions on the use of erosive land will also lead to increased rents for less erosive lands. The increased cost of land remaining in production relative to capital and labor encourages the substitution of capital and labor for land or a shift to more intensive production on the land remaining in production. The net effect of these forces in the alternatives analyzed in this study is an increase in capital and labor employed in agriculture (table 5). The problem that is not addressed is the transfer within agriculture. The magnitude and the difficulty of achieving this transfer depends upon the particular form



Each dot = 50,000 acres

Figure 2. Location of idle cropland in the soil conservation alternative (Alternative B)



Each dot = 500,000 acres

Figure 3. Location of idle cropland in the conservation land retirement alternative (Alternative D)

of the policy. Issues that affect this transfer include whether the policy is short- or long-term, whether there is partial or whole farm retirement, and the opportunity returns available for labor and capital.

Another issue is the potential impact of this capital and labor transfer on rural communities. Many rural communities depend on providing services and inputs for the local farm sector. Whole farm retirement in erosive areas, for example, could have severe ramifications for the nonfarm sector of communities.

No estimate was made of the administrative or enforcement costs of the various policies. The costs of inventorying land, measuring soil erosion, enforcing compliance, etc., could be extremely large unless efficient administrative methods are developed. This area needs additional research, especially since Section 208 of the 1972 Federal Water Pollution Control Act Amendments requires states to develop plans for controlling nonpoint pollution from agriculture and silvaculture.

Throughout, this study concentrated on gross soil erosion and application rates of fertilizers and chemicals rather than on direct measures of environmental quality. There are two reasons for this approach. First, soil conservation is an important objective in itself. Second, national information needed to relate gross soil erosion and rates of chemical applications directly to measures of environmental quality is currently unavailable.

Conclusions

This study indicates that a conservation-oriented land retirement policy can be de-

signed to achieve an increase in net farm income equivalent to the traditional type of general land retirement, while simultaneously achieving a significant reduction in gross soil erosion. In addition, these results can be obtained with fewer chemical inputs and a significantly smaller direct program cost for the government. More important perhaps is that the analysis demonstrates the economic potential of analyzing and coordinating various agricultural policies and policy combinations.

The separable programming model utilized in this study provides a flexible and useful tool for policy analysis. It yields much information of the type and detail necessary for effective planning. The results, however, need to be interpreted in relation to the strengths and limitations of the model. The model is a normative, comparative static, mathematical programming model with all its standard limiting assumptions. In addition, its sheer size — while the source of much of its usefulness, flexibility, and capacity — presents significant data and programming requirements. Finally, as always, the results can be no better than data on which they are based.

Net Investment in Farm Tractors: An Econometric Analysis

John B. Penson, Jr., Robert F. J. Romain, and Dean W. Hughes

A wide range of assumptions about the capital deterioration and marginal factor cost of tractors has been made in previous studies. This study develops a measure of the implicit rental price of tractors which accounts for the capital structure used by farmers, the capacity depreciation of tractors, and income tax considerations. Estimates of net investment models for alternative capacity depreciation patterns are compared to those suggested by engineering considerations. The results show that the frequently used geometric decay pattern does the poorest job of explaining annual real net investment in farm tractors.

Key words: capacity depreciation, implicit rental price, real net investment.

There were numerous econometric studies of aggregate investment behavior in the U.S. farm sector conducted during the 1950s and 1960s. While these studies investigated a wide range of durable inputs, the input receiving the most attention was farm tractors. Several questionable assumptions in these studies, however, have a direct bearing on the specification, measurement, and estimation of their statistical models. For example, each study had to assume how the productive capacity of farm tractors depreciates over their service lives since the actual capacity depreciation pattern is not known. Cromarty assumed the productive capacity of a tractor is much like that of a light bulb; it does not decline at all until the final year of its service life. Heady and Tweeten assumed farm tractors wear out in a geometric decay fashion. Finally, Griliches examined the difference between the regression estimates based upon these two capacity depreciation patterns, concluding that "the truth may lie somewhere in between these two extremes" (p. 202). The productive capacity of the stock of tractors on farms in these studies differs sharply from that reported by Penson, Hughes, and Nelson, who estimated a capacity depreciation pattern for tractors based upon engineering data. Their estimated pattern fell in between the pattern assumed by Cromarty and the pattern assumed by Heady and Tweeten, as Griliches supposed. It was also concave rather than convex, as suggested by the geometric decay pattern. This leads to large differences in the annual data for net investment and the existing capital stock, as Penson, Hughes, and Nelson show.

Measures of the marginal factor cost of tractors in previous studies did not include all the investment costs suggested by maximization of the present value of owner equity. Cromarty considered only the purchase price of the farm tractor. Griliches included both the purchase price and the nominal interest rate. All, however, appear to have ignored the real after-tax cost of borrowing, investment tax credit, tax depreciation allowances, and the real after-tax cost of owner equity capital.

The purpose of this paper is to develop and test an econometric model of annual real net investment in farm tractors. The implicit rental price of capital advanced by Coen is modified to reflect the capital structure farmers follow when financing purchases of durable inputs. Emphasis is placed on determining which of the frequently assumed capacity depreciation patterns most closely approximates the statistical estimates based on the engineering data pattern developed by Penson, Hughes, and Nelson.

John B. Penson, Jr. is a visiting scholar at the Federal Reserve Bank of Kansas City, on leave from Texas A&M University; Robert F. J. Romain is a research assistant at Texas A&M University; and Dean W. Hughes is a business economist at the Federal Reserve Bank of Kansas City.

Determinants of Net Investment

The aggregate investment behavior model used here was developed initially from the

theory of the firm in continuous equilibrium. Conditions of perfect competition and knowledge were assumed. Then, recognizing that perfect knowledge does not exist and lags in investment response do, the model was modified to include the adaptive expectations and partial adjustment hypotheses.

Desired Stock of Farm Tractors

If, when making investment decisions, farmers maximize the present value of equity, they would continue to add to their existing stock of plant and equipment as long as the present value of the periodic net cash flows generated by an additional unit exceeds the net purchase price of the input. For tractors, this can be stated algebraically as follows:

$$(1)\quad \sum_{t=1}^{\infty} [p(\partial X/\partial K_j^T) - (\partial T_t/\partial K_j^T) - r(\partial D/\partial K_j^T) - (\partial P/\partial K_j^T)]\,(1+\rho)^{-t} > q^T(\alpha - i_c)[1 + \sum_{t=1}^{\infty} (\partial R_{jt}^T/\partial K_j^T)(1+\rho)^{-t}],$$

where

$$(2)\quad (\partial T_t/\partial K_j^T) = i_\pi\{p(\partial X/\partial K_j^T) - r(\partial D/\partial K_j^T) - q^T[\delta(1-\delta)^{t-1} + \sum_{i=1}^{t} \delta(1-\delta)^{i-1}(\partial R_{jt-i}^T/\partial K_j^T)]\},$$

and where p represents the real price farmers receive per unit of output, X is the real value of farm output, K_j^T is the real stock of farm tractors measured according to the jth capacity depreciation pattern, T_t is the income taxes paid in period t expressed in constant dollars, r is the real rate of interest on debt capital, D represents debt outstanding, P is the principal payment expressed in constant dollars, ρ is the real after-tax opportunity rate of return on equity capital desired by farmers, q^T is the real price paid for farm tractors at the retail level, α is the proportion of the investment financed with equity capital, i_c is the investment tax credit rate, R_{jt}^T represents the real level of replacement investment required in period t according to the jth capacity depreciation pattern, i_π is the income tax rate, and δ represents the tax depreciation rate given by $2/n$, where n is the service life of the tractor.

The first term on the left-hand side of equation (1) is the real marginal net revenue excluding interest payments associated with financing a new tractor. The second term is the increase in income taxes expressed in constant dollars, while the third and fourth terms are the interest and principal payments associated with the loan on the investment, respectively. The right-hand side is the initial cash outflow—down payment minus the investment tax credit—plus the present value of all future cash outflows necessary to maintain the capital stock at its new level. Equation (2) gives the increase in income taxes generated by a new tractor—marginal net revenue minus interest payments and tax depreciation allowances on the new unit and its replacements, all multiplied by the income tax rate.

Both the principal and interest payments $[r(\partial D/\partial K_j^T)$ and $(\partial P/\partial K_j^T)]$ are constant over time because of our assumption that all future replacement investments necessary to maintain the capital stock at its new level are financed the same way as the original investment. We also assume the length of the loan period is the same as the service life of the tractor and that farmers expect real prices (p), real interest rates (r), and the marginal physical product of tractors $(\partial X/\partial K_j^T)$ to remain at current levels. These last two assumptions are similar to Coen's. All three allow us to treat components of equation (1) as consols, greatly simplifying the analysis.

Maximization of the present value of owner equity under the conditions assumed above, according to Coen, requires that

$$(3)\qquad (\partial X/\partial K_j^T) = c_j^T/p,$$

where c_j^T is the implicit rental price of tractors associated with the jth capacity depreciation pattern. Assume that farm output is produced according to the production function,

$$(4)\qquad X = AL^{\phi}(K_j^T)^{\beta}(K_j^o)^{\gamma}(K^{\ell})^{\omega}(K^{v})^{\epsilon},$$

where L represents the labor input, K_j^T represents the real stock of tractors measured according to the jth capacity depreciation pattern, K_j^o represents the real stock of other durable inputs measured according to the jth capacity depreciation pattern, K^{ℓ} represents land, K^v represents the variable production inputs used to produce farm output, and ϕ, β, γ, ω, and ϵ are partial production elasticities associated with L, K_j^T, K_j^o, K^{ℓ}, and K^v, respectively.[1] This, of course, means that the margi-

[1] The real productive value of the existing stock of farm tractors measured according to the jth capacity depreciation pattern is defined later in equation (14). As $\Sigma_k \xi_i$ in that equation approaches 1.0, the remaining fraction of the original productive capacity of tractors purchased in year $t-k$ approaches zero.

nal physical product for tractors is

$$(5) \qquad (\partial X/\partial K_j^\tau) = \beta(X/K_j^\tau).$$

Substituting equation (5) into equation (3), we see that the desired stock of tractors, according to the jth capacity depreciation pattern, would be

$$(6) \qquad K_j^{\tau *} = \beta(pX/c_j^\tau)^*,$$

where c_j^τ represents the implicit rental price of tractors associated with the jth capacity depreciation pattern. Equation (6) implies that the desired stock of tractors is positively affected by expected real gross income from farming and negatively affected by the expected implicit rental price for tractors. Similar equations also could be developed for other inputs in equation (4).

Implicit Rental Price of Tractors

A recent innovation in aggregate investment behavior analysis is the concept of the implicit rental price of capital. Coen has advanced this concept in studies of aggregate investment behavior in the U.S. manufacturing sector. An appealing feature of Coen's work is his explicit accounting of the effects that alternative capacity depreciation patterns have upon marginal factor costs of durable inputs. Coen, however, ignores debt financing and the deductibility of interest payments. In the farm sector, where the use of debt capital relative to owner equity rose dramatically during the 1970s, such an omission could seriously understate the implicit rental price of tractors (Penson).

To measure the implicit rental price of capital, accounting for both debt and owner equity financing of capital expenditures, we must solve initially for the marginal value product of tractors. Substituting equation (2) into equation (1) and solving for $p(\partial X/\partial K_j^\tau)$, we see that

$$(7) \quad p(\partial X/\partial K_j^\tau) = \frac{1}{(1 + i_\pi)} \Bigg[\Bigg\{\rho q^\tau(\alpha - i_c)\Bigg[1 + \sum_{t=1}^{\infty} (\partial R_{jt}^\tau/\partial K_j^\tau)(1 + \rho)^{-t}\Bigg]\Bigg\} - q^\tau i_\pi \Bigg\{\sum_{t=1}^{\infty} \delta(1 - \delta)^{i-1}(1 + \rho)^{-t} + \sum_{t=1}^{\infty} \Bigg[\sum_{i=1}^{t} \delta(1 - \delta)^{i-1}(\partial R_{jt-i}^\tau/\partial K_j^\tau)\Bigg] (1 + \rho)^{-t}\Bigg\} + Z - i_\pi r\psi\Bigg],$$

where Z represents the value of the periodic loan payment (principal plus interest) and ψ is the fraction of the purchase price financed with debt capital (i.e., $\psi = 1 - \alpha$).

Multiplying both sides of equation (3) by p and substituting the right-hand side of equation (7) into the resulting equation, it can be shown that

$$(8) \quad c_j^\tau = [(q^\tau\rho)/(1 - F_j)] [\alpha - i_c - i_\pi\{\delta/(\delta + \rho)\}]/(1 - i_\pi) + (Z - i_\pi r\psi)/(1 - i_\pi),$$

where

$$(9) \qquad F_j = \sum_{i=1}^{\infty} h_{ji}(1 + \rho)^{-i},$$

$$(10) \quad 1/(1 - F_j) = 1 + \sum_{t=1}^{\infty} (\partial R_{jt}^\tau/\partial K_j^\tau)(1 + \rho)^{-t},$$

$$(11) \quad \delta/(\delta + \rho) = \sum_{t=1}^{\infty} \delta(1 - \delta)^{t-1}(1 + \rho)^{-t},$$

and where F_j is the present value of the stream of capacity depreciation of a tractor associated with the jth capacity depreciation pattern and h_{ji} is the fraction of the tractor's original productive capacity lost in the ith year of its service life according to the jth capacity depreciation pattern. Equation (8) suggests that the implicit rental price of tractors will increase if their purchase price, the cost of debt and equity capital, capacity depreciation, or income tax rates increase. These effects will be offset to some extent by an increase in the investment tax credit rate and the deductibility of tax depreciation allowances and interest payments. The implicit rental price of tractors presented in equation (8) is a sharp contrast to the measures of the marginal factor cost specified in previous studies.

Desired Net Investment in Tractors

Annual gross investment for any durable input can be partitioned into replacement investment and net investment. Replacement at the sector level is the expenditure required to restore losses in the productive capacity of the existing capital stock, while net investment is the expenditure to expand the existing stock. More explicitly, net investment in tractors,

measured according to the jth capacity depreciation pattern, is

$$(12)\quad N_{jt}^{\tau} = K_{jt+1}^{\tau} - K_{jt}^{\tau} = I_t^{\tau} - R_{jt}^{\tau},$$

where

$$(13)\quad R_{jt}^{\tau} = \sum_{k=0}^{\infty} h_{jk+1} I_{t-k}^{\tau},$$

$$(14)\quad K_{jt}^{\tau} = \sum_{k=1}^{\infty} (1 - \sum_{i=1}^{k} h_{ji})\, I_{t-k}^{\tau},$$

and I_t^{τ} represents the level of real gross investment in tractors during the year, R_{jt}^{τ} is the real replacement investment needed according to the jth capacity depreciation pattern, and h_{ji} is the fraction of the tractor's original capacity lost in the ith year of its service life. Equation (12) states that the net expansion of farm tractor capacity is equal to the net change in the real productive value of the stock of tractors between successive accounting dates. This equation assumes that tractors are originally purchased at the beginning of the year and, therefore, depreciate by a factor of h_{ji} in their first period of ownership.

Substituting equation (6) into equation (12), we can show that if the adjustment from actual to desired stocks is completed within time period t, the desired expansion of farm tractor capacity is given by

$$(15)\quad N_{jt}^{\tau *} = \beta(pX/c_j^{\tau})_t^{*} - K_{jt}^{\tau}.$$

The amount of time necessary to adjust from current to desired stocks, however, may be longer than one period, due to institutional rigidities and other factors, Also, little is known about how farmers form expectations about the value of farm output and the implicit rental price of durable inputs.

Statistical and Measurement Procedures

The approach taken in this study to account for the adjustment to desired stocks and the formation of expectations by farmers is to utilize the compound geometric lag model described by Kmenta.

Statistical Model

The relationship between the desired stock of tractors and current real net investment, measured according to the jth capacity depreciation pattern, is

$$(16)\quad N_{jt}^{\tau} = \Theta_j^{\tau}(K_{jt+1}^{\tau *} - K_{jt}^{\tau}),$$

where $0 < \Theta_j^{\tau} \leq 1$, and Θ_j^{τ} represents the partial adjustment coefficient that describes the speed of adjustment of actual stocks to desired levels measured according to the jth capacity depreciation pattern. If $\Theta_j^{\tau} = 1$, then $N_{jt}^{\tau} = N_{jt}^{\tau *}$. Substituting equation (6) into equation (16), we see that

$$(17)\quad N_{jt}^{\tau} = \Theta_j^{\tau}\beta(pX/c_j^{\tau})_t^{*} - \Theta_j^{\tau}K_{jt}^{\tau}.$$

If we further assume an adaptive expectations hypothesis of the form

$$(18)\quad (pX/c_j^{\tau})_t^{*} - (pX/c_j^{\tau})_{t-1}^{*} = \lambda_j^{\tau}[(pX/c_j^{\tau})_t - (pX/c_j^{\tau})_{t-1}^{*}],$$

where $0 < \lambda_j^{\tau} \leq 1$, and λ_j^{τ} is the adaptive expectations coefficient, then the estimating equation would be

$$(19)\quad N_{jt}^{\tau} = \Theta_j^{\tau}\beta\lambda_j^{\tau}(pX/c_j^{\tau})_t + (1 - \lambda_j^{\tau})\, N_{jt-1}^{\tau} + \Theta_j^{\tau}(1 - \lambda_j^{\tau})K_{jt-1}^{\tau} - \Theta_j^{\tau}K_{jt}^{\tau} + \mu_t.$$

Since K_{jt-1}^{τ} is, by definition, equal to $K_{jt}^{\tau} - N_{jt-1}^{\tau}$, equation (19) reduces to

$$(20)\quad N_{jt}^{\tau} = b_0 + b_1(pX/c_j^{\tau})_t + b_2K_{jt}^{\tau} + b_3N_{jt-1}^{\tau} + \mu_t,$$

where $b_1 = \Theta_j^{\tau}\beta\lambda_j^{\tau}$, $b_2 = -\Theta_j^{\tau}(1 - \lambda_j^{\tau})$, $b_3 = (1 - \lambda_j^{\tau})(1 - \Theta_j^{\tau})$, and μ_t represents the disturbance term. The estimates of the b_1 and b_3 coefficients should therefore be positive, while b_2 should be negative. The b_0 coefficient is included here because we are not entirely sure a priori that the intercept should be zero.

Data

The time series used in this study are annual observations over the 1950–78 period. Many appear in publications of the U.S. Department of Agriculture (USDA); others are published by the U.S. Department of Commerce.

The annual levels of nominal gross investment in farm tractors published by the U.S. Department of Agriculture (USDA 1979b) were deflated to real terms by an unpublished fixed weight index of prices paid for farm tractors provided by the U.S. Department of Agriculture (I_t^{τ}).

The values for the h_{ji} weights for the engineering data (ED) capacity depreciation pattern are those reported by Penson, Hughes, and Nelson. Three frequently assumed capacity depreciation patterns are also examined in

this study. The values for the h_{ji} weights for the geometric decay (GD) pattern assumed by Heady and Tweeten are given by $\Phi(1 - \Phi)^{i-1}$, where $\Phi = 2/n$ and $n = 15$. The h_{ji} weights for the capacity depreciation pattern assumed by Cromarty are equal to 0 for $i = 1, \ldots, 14$, and 1 when $i = 15$. Likened to the wear-out of a light bulb earlier in this paper, this capacity depreciation pattern is referred to as the one-hoss shay (OHS) pattern by both Griliches and Coen because there is no deterioration in service until it is scrapped. Finally, the h_{ji} weights for the straight-line (SL) capacity depreciation pattern examined by Coen are equal to $1/n$, where $n = 15$.

The annual values for c_j^τ are found by using these h_{ji} weights in conjunction with equation (9) and then substituting the values of F_j into equation (8). We have followed Coen in assuming the real after-tax rate of return desired by farmers on their equity capital (ρ) is constant over the economic life of the investment (Coen, p. 63). The rate of interest on non-real estate loans at commercial banks was used to compute the real cost of debt capital (r). The time-series values for ψ were found by dividing the change in total farm debt by the level of gross investment in durable inputs reported by the USDA (1979a,b). The time series for α, the fraction of capital expenditures for durable inputs financed with internal equity capital, is equal to $1 - \psi$. Finally, the periodic loan payment (Z) was computed by dividing $q^\tau(1 - \alpha)$ by the equal-payment interest factor for r and n.

The quality of the time series for N_{jt}^τ and K_{jt}^τ depends upon how well the values of I_t^τ reflect quality changes in tractors over time. The deflated expenditure series should reflect changes in tractor horsepower over time since the USDA computes a fixed-weight prices-paid index based on information for five size and type categories of tractors. Using this index also guarantees that the deflated expenditure series also will reflect other technological improvements captured in the cost of the tractor. To the extent that some quality changes are not reflected in the cost of tractors, the coefficient estimates presented in the following section will reflect measurement er-

Choice of Estimator

The net investment model given by equation (20) can be viewed as a part of a simultaneous system of equations that includes other investment equations as well as supply equations for all inputs and the production function outlined in equation (4).[2] However, ordinary least squares (OLS) was used to estimate the b_i coefficients. The reasons for doing so were originally articulated by Griliches. Tractor purchases are "unlikely to influence agricultural product prices in the short run, both because the output effect of these purchases is likely to be small and because agricultural output is subject to relatively large random (weather) fluctuations" (Griliches, p. 188). And, the price paid for tractors, as a component of c_j^τ, is assumed to be predetermined since "tractors are produced and sold by a few major firms that announce their price early in the model year and rarely vary it within the season" (Griliches, p. 189). Thus, p, X, and c_j^τ are assumed to be predetermined.

To assess the effects of this assumption, a simultaneous equations estimator was used to estimate the coefficients in equation (20) for the ED pattern. Because there were more predetermined variables in this simultaneous system of equations than observations (n), the structurally oriented instrumental variable (SOIV) estimator, originally proposed by Fisher, was employed. SOIV is more efficient than some other "large model" estimators like two-stage principal components because it orders the predetermined variables in the model according to how closely associated they are with the explanation of p, X, and c_j^τ. The first $n - 1$ predetermined variables are then used to obtain first-stage estimates of these variables, which in turn are used in a second-stage OLS estimation of the coefficients in equation (20). For an indepth evaluation of this estimator, see Mitchell or Brundy and Jorgenson.

---

[2] The input supply equations include not only the endogenously determined retail input price, but other variables like the capacity utilization index of the manufacturing sector and wholesale prices of raw materials. Stock demand equations for financial assets as well as real estate and non-real estate debt capital also can be

Empirical Results

The OLS and SOIV estimates of the b_i coefficients in equation (20) for the ED pattern are presented in table 1. Each coefficient has the expected sign and is significantly different from zero at the 10% level or less. The R^2 of .861 suggests that the variables in equation (20) do a good job of explaining annual real net investment in tractors. There is also no significant difference between the coefficient estimates given by the OLS and SOIV estimators since the R^2s in the first stage of the SOIV estimator were almost 1.0. This supports our use of OLS for the other capacity depreciation patterns. This conclusion is specific to this study and may not be general.

The OLS estimates of the b_i coefficients for the GD, OHS, and SL capacity-depreciation patterns reported in table 1 also had the expected signs. Note the coefficient associated with the lagged capital stock in the OHS equation was not significantly different from zero at the 10% level. Finally, we failed to reject the hypothesis of zero autocorrelation at the 5% level in all the equations in table 1 based upon an evaluation of the Durbin h-test statistic. Thus, no correction for autocorrelation was required.

A comparison of the R^2 values for the capacity depreciation patterns investigated in this study confirms both the results found by Coen and our hypothesis that the ED pattern most closely influences actual capital spending decisions. First, the R^2 associated with the SL pattern (.781) was higher than those for the OHS pattern (.774) and the GD pattern (.666). This is the same ordering Coen found for real net investment in equipment by manufacturing firms. However, the R^2 for the ED pattern (.861) was even higher. It appears, therefore, that both the SL and OHS patterns are better proxies for capital deterioration suggested by engineering considerations than the frequently used GD pattern.

We can compare these patterns further by examining the elasticities associated with the $(pX'c_j^T)$ variable, computed at the mean. The elasticity for the ED pattern was 2.64. This same elasticity for the OHS, SL, and GD patterns was 2.53, 4.33, and 6.59, respectively. Thus, the OHS and SL most closely approximate that of the ED pattern. The elasticity associated with the GD pattern substantially overestimates farmers' investment responses to changes in prices, interest rates, taxes, and other relevant variables.

We can also examine the assumption of Peterson and Hayami (constant service flow over a machine's life) by calculating the partial production elasticity for tractors, or β in equation (4), and comparing it to the β coefficient of the ED pattern. This elasticity for the jth capacity depreciation pattern is given by $-b_{1j}/b_{2j}$. The partial production elasticity for tractors with the ED pattern was .0303, while that for the OHS pattern was .0333. This result thus lends support to the Peterson-Hayami assumption of constant annual service flows. However, the coefficient on the lagged capital stock in the OHS equation was not significantly different from zero at the 10% level. Both of these elasticities were more than double that calculated for the GD pattern (.0123).

Table 1. SOIV and OLS Estimates of the Coefficients in the Real Net Investment Model Described in Equation (20)

Capacity Depreciation Pattern	b_0	b_1	b_2	b_3	R^2
Engineering data pattern (ED)					
SOIV estimator	−.063533	.001226	−.040470	.680080	.861
	(.267565)[a]	(.000279)	(.022219)	(.094767)	
OLS estimator	−.064095	.001277	−.040481	.679792	.861
	(.267625)	(.000280)	(.022223)	(.094810)	
Straight-line pattern (SL)					
OLS estimator	−.014116	.001486	−.066825	.532891	.781
	(.187595)	(.000334)	(.028846)	(.121163)	
One-hoss shay pattern (OHS)					
OLS estimator	−.083466	.001187	−.035510	.666579	.774
	(.381876)	(.000359)	(.028933)	(.118693)	
Geometric decay pattern (GD)					
OLS estimator	−.067464	.001094	−.088872	.339704	.666
	(.149014)	(.000250)	(.037363)	(.145518)	

[a] Figures in parentheses are the standard errors associated with the coefficients.

Considering the partial production elasticity for all machinery and equipment calculated by Shumway, Talpaz, and Beattie (.1335) during 1967–76, it appears the GD pattern substantially understates the role played by tractors in agricultural production. Finally, the partial production elasticity for tractors with the SL pattern (.0222) was considerably lower than the elasticity with the ED pattern.

In summary, the explanatory variables in equation (20) did a good job of explaining annual variations in real net investment in farm tractors over the 1950–78 period when the ED capacity depreciation pattern was used. While the GD pattern is easiest to implement because time-series data for R_j^τ and K_j^τ are readily available and the specification of c_j^τ is relatively simple, it represents the poorest proxy for the capacity depreciation pattern suggested by engineering considerations. If an estimate of the ED pattern is not available for a particular durable input, the results from this study and Coen's show that the OHS and SL patterns do a better job of approximating capital deterioration in aggregate investment analysis than the frequently used GD pattern.

The Economic Feasibility of Crop Residues as Auxiliary Fuel in Coal-Fired Power Plants

Burton C. English, Cameron Short, and Earl O. Heady

Rising fossil fuel costs spark interest in crop residues as a renewable energy source. Residue costs for combustion in power plants are estimated in 1975 prices to evaluate their feasibility. Costs are estimated for farm production, transportation, and processing and handling at the energy recovery level. They are incorporated into an Iowa agricultural programming model which includes an electric utility sector. The model, including crop production, is solved for several scenarios—a base solution, energy price increases, and a sulfur constraint. Under these scenarios, crop residue replaces coal at 20%, 40%, and 60% of the 1975 Btu's consumed.

Key words: biomass, crop residue, Iowa Linear Programming Model.

Energy production from renewable resources is being discussed and examined. New technologies are being developed to use these renewable resources in fuel production. The United States is a nation rich in domestic energy resources, yet large quantities of energy are imported. Exxon Corporation examined the world's energy situation and concluded that a significant shift in the shares of energy supplied by various fuels could occur by 1990. In addition, they concurred with the Project Independence Task Force that synthetic fuel, solar, and other energy forms could be the basis for rapid expansion in future energy supplies. This paper examines a solar-based energy supply.

Crops capture solar energy, a flow resource, and combine it with other elements such as plant nutrients, water, and carbon dioxide to form grains, fruits, and fibers. A future purpose of U.S. agriculture also may be to provide energy. Significant amounts of energy in excess of food and fiber requirements may come from energy crops, agricultural by-products, crop residues, and animal wastes.

These products and by-products of the agricultural production process are forms of biomass. Biomass consists of carbon-to-carbon bonds. It is in these bonds that energy is stored and may be released to provide crucial fuels in the future.

The primary fuel stock considered here is crop residue, principally of the stalks and leaves of crops such as corn grown for grain. Now, some of these residues are removed or used in situs for livestock feed. For the most part, crop residues are incorporated into the soil. For every 16 kilocalories (kcal) produced through the capturing of energy by plants, 3.9 kcal are inherent in the residues left after harvesting (Nelson, Burrows, and Stickler). Some or all of the residues left in the field are useful for soil conservation, but also may have potential as a renewable energy source.

Objectives

This study examines the economic feasibility of using crop residues for direct combustion in Iowa's electrical generating power plants. A maximizing linear programming model representing Iowa's agricultural sector and electricity-producing complex is used to assess economic feasibility. The economic feasibility is evaluated with three different possible future scenarios: the Base, Increased Energy Prices, and Reduced Sulfur Emis-

Burton C. English and Cameron Short are a research economist and a staff economist, respectively, at the Center for Agricultural and Rural Development. Earl O. Heady is a Distinguished Professor at Iowa State and Director of the Center for Agricultural and Rural Development.

This is Journal Paper No. J9810 of the Iowa Agriculture and Home Economics Experiment Station, Project 2105.

sions. Under each of these scenarios, crop residues are substituted for 0%, 20%, 40%, and 60% levels of coal consumed in 1975 by Iowa's power plants. The Base assumes 1975 costs, average 1970–75 yields and production prices, and 1975 sulfur emissions regulations. Both of the other scenarios assume a doubling of 1975 retail energy prices. Sulfur emissions are constrained in all solutions; current standards are used for sulfur for all scenarios except the Reduced Sulfur Emission where more restrictive standards are used along with doubled energy prices.

Study Area and Model

Iowa is selected as the study area because it has a high density of crop residues, and its electric utilities are dispersed. Iowa is divided into twelve agricultural producing regions consistent with Iowa's soil conservancy districts, and nineteen utility sectors (fig. 1). Small utilities (with an annual output of less than 5.0 megawatts) are not incorporated into the model as the fixed costs of processing residue for these power plants may be prohibitive. (Incorporation of small power plants would not affect overall results because of the small amount of residues that would be used.)

The linear programming model used in this study can be divided into two main components linked together by the production and use of crop residues. The model maximizes the net returns to crop production in Iowa and minimizes the costs of supplying coal and crop residues to Iowa power plants. A detailed description of the main components of the model is given in English et al., but the main structure of each component is described below.

The power plant component is similar to a feed mix model, where the "feeds" are a number of different coals and crop residues to be combined so that the fuel needs of the power plant are satisfied, the sulfur emission standards met, and costs minimized. The objective for the power plant sector is

$$(1)\quad \max = \sum_{n} \sum_{m} P_{nm}^{c}\, Q_{nm}^{c} - \sum_{m} P_{n}^{r} R_{m}^{r},$$

and is subject to m fuel constraints:

$$(2)\qquad B_{n}^{c} Q_{nm}^{c} + B_{n}^{r} R_{m}^{r} \geq BTU_{m}.$$

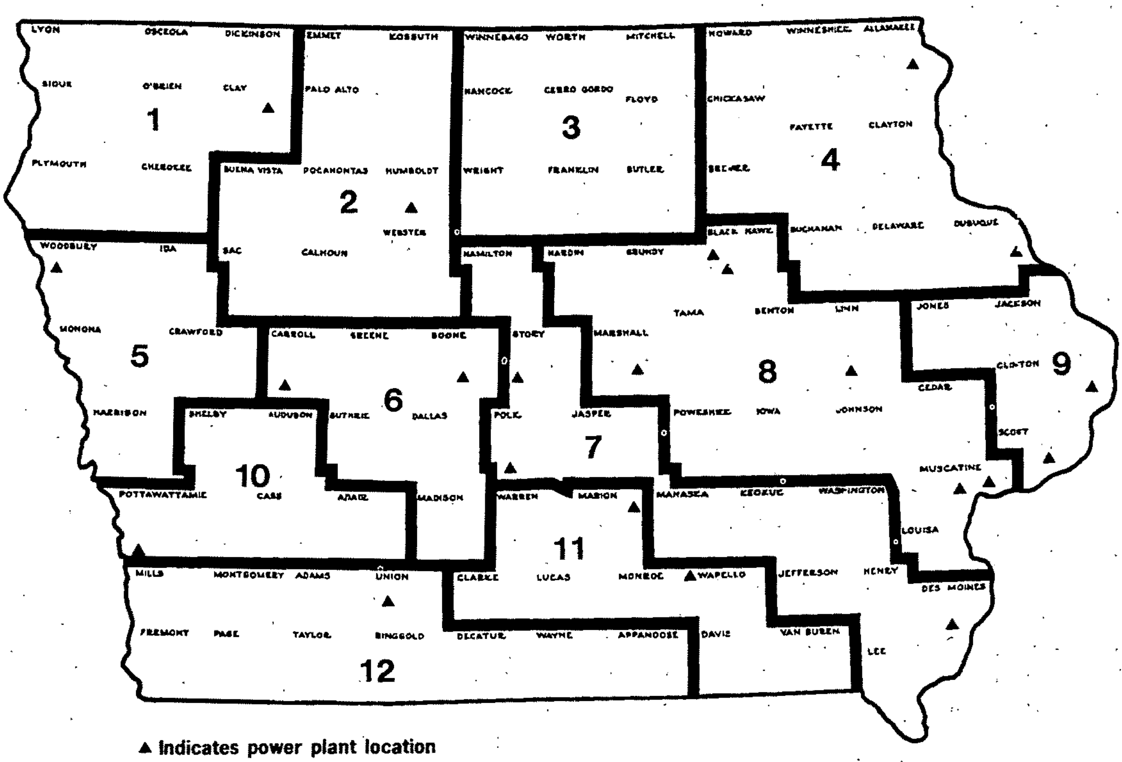

Figure 1. Twelve agricultural regions and power plant location

m emission constraints;

$$(3) \qquad S_n{}^c Q_{nm}{}^c + S_n{}^r R_m{}^r \leq SO2_m,$$

and m crop residue constraints;

$$(4) \qquad B^r R_m{}^r \geq (PROP)\ BTU_m,$$

where n = 1 to 9 for 9 coal types and m = 1 to 18 for 18 power plant locations; $P_{nm}{}^c\ Q_{nm}{}^c$ is the cost of coal n to power plant m; $P_m{}^r R_m{}^r$ is the cost of crop residues to power plant m; $B_n{}^c\ Q_{nm}{}^c$ is the heating value of coal n to power plant m; $B_m{}^r R_m{}^r$ is the heating value of crop residue to power plant m; $S_n{}^c\ Q_{nm}{}^c$ is the sulfur emissions generated from coal n at power plant m; $S_n{}^r\ R_m{}^r$ is the sulfur emissions generated from crop residue at power plant m; BTU_m is the quantity of fuel required by power plant m; $SO2_m$ is the maximum sulfur emissions allowed at power plant m for the fuel quantity BTU_m; and $PROP$ is the proportion of fuel supplied by crop residues.

The value for the proportion of energy supplied by crop residues is parametized over the values 0.0, 0.2, 0.4, and 0.6, with changes in the objective function coefficients made to reflect size economies in crop residues. The coal types include both washed and unwashed coal from Iowa and other midwestern states and low sulfur western coal from Wyoming.

For several reasons, 60% was selected as the upper limit on the amount of coal to be replaced with crop residues. Green estimates that up to 60% of the coal could be replaced before particular emission standards would be exceeded without additional particulate collectors. Crop residues also have lower density than most coals, so a reduction of boiler capacity is likely where power plant boilers are designed to close specifications for a low ash-high BTU coal. For older traveling grate furnaces in Iowa, the 60% limit is a reasonable approximation of the amount of coal that can be replaced.[1] However, early attempts at burning MSW in suspension boilers were successful only in very large units but the installation of a dump grate in the bottom of two Ames suspension boilers allowed 20%–25% of the coal to be replaced and further modifications are expected to raise this limit to 30%. Thus, the upper limit of 60% coal replacement with crop residues for retrofitting boilers in Iowa is a maximum with likely technology in the near future and may not be feasible without derating some of the boilers. Only costs of boiler modification similar to those incurred in Ames are included in the objective function.

The crop production component maximizes returns to crop production defined as returns to land and management:

$$\max = \sum_i \sum_j P_{ij}{}^a Q_{ij}{}^a - \sum_h \sum_j \sum_k \sum_l (T_{hjkl}{}^a L_{hjkl}{}^a T_{hjkl}{}^r L_{hjkl}{}^r),$$

subject to 2 jl land constraints;

$$\sum_h \sum_k (L_{hjkl}{}^a + L_{hjkl}{}^r) \leq L_{jl}, \text{ and}$$

$$\sum_h \sum_k L_{hjkl}{}^r \leq L_{jl}{}^r,$$

ij production constraints;

$$Q_{ij}{}^l + Q_{ij}{}^a \leq \sum_h \sum_k \sum_l (Y_{hjkl}{}^l L_{hjkl}{}^a + Y_{hjkl}{}^a\ L_{hjkl}{}^r),$$

2 j crop residue constraints;

$$R_j{}^l \leq \sum_h \sum_l \sum_k Y_{hjkl}{}^r\ L_{hjkl}{}^a,$$

$$\sum_m R_{mj}{}^r \leq \sum_h \sum_l \sum_k Y_{hjkl}{}^r\ L_{hjkl}{}^r,$$

and soil loss is estimated by

$$S = \sum_h \sum_j \sum_k \sum_l (S_{hjkl}{}^a\ L_{hjkl}{}^a + S_{hjkl}{}^r\ L_{hjkl}{}^r),$$

where i = 1 to 8 for crops produced, j = 1 to 12 for 12 producing areas, h = 1 to 40 for crop rotations, k = 1 to 12 for 12 conservation and tillage practices, l = 1 to 5 for 5 land classes, and m = 1 to 18 for the power plants; $P_{ij}Q_{ij}$ is the value of crop i produced in producing area j; $T_{hjkl}{}^a L_{hjkl}{}^a$ is the cost of production for rotation h in region j with conservation/tillage practice k on land class l with crop residues removed for combustion in power plants; $L_{hjkl}{}^a$, $L_{hjkl}{}^r$ are the amounts of land used for rotation h in region j with conservation/tillage practice k on land class l without and with the removal of crop residues for combustion, respectively; L_{jl} is the total amount of land available in region j, land class l; $L_{jl}{}^r$ is the total amount of land available in the power plant collection areas; $Y_{hjkl}{}^i$ is the yield per rotation acre of crop i in rotation h, region j, with conservation/tillage practice k on land

[1] As stated by Merlin Hove, City of Ames, Iowa, the traveling grate furnaces in Ames have successfully operated with up to 60% of the coal replaced with municipal solid waste.

class l; $Q_{ij}{}^l$ is the amount of crop i required for livestock feed in region j; $Q_{ij}{}^a$ is the amount of crop i sold in region j; $Y_{hjkl}{}^r$ is the harvested residue yield per rotation acre for rotation h in region j, with conservation/tillage practice k on land class l; $R_j{}^l$ is the amount of residues required as livestock roughage in region j;[2] $R_{mj}{}^r$ is the amount of residues required by power plant location m in region j; $S_{hjkl}{}^a$, $S_{hjkl}{}^r$ are the soil losses generated by rotation k in region j, with conservation/tillage practice k on land class l for rotations in which residues are removed and without residues removed, respectively; and S is the total amount of soil loss.

Net agricultural returns can be derived by subtracting the objective function for the power plant component from the overall objective function. The costs of producing agricultural commodities included in the objective function coefficients consist of labor, machinery, pesticides, energy, and fertilizers. Returns to land and management are determined endogenously by the model. The agricultural sector uses energy in the production and harvesting of crops: direct energy requirements for machine operation and crop drying are computed and indirect requirements of energy for agricultural chemicals are included. The use of coal and crop residues requires energy; and finally, the power plant component uses energy for transportation and processing. The amount of energy by fuel type is quantified as an important result and is needed to change objective function values for the scenario displaying increased energy prices.

Crop Residue Costs

The costs of crop residues are estimated for three stages of crop residue production and energy conversion—farm level, transportation, and processing and handling at the power plant. Costs included in the farm level stage are harvesting and agronomic costs with initial storage of the residues assumed to occur on the farm. Transportation costs are estimated as a function of unit transportation costs and the size and shape of the collection area, the latter depending on the location and size of the plant. Processing and handling costs at the power plant include capital investment in buildings and equipment, wages, and operation and maintenance costs. The processing and handling system requires both the reduction of residues to a homogenous size and short-term residue storage. Processing and handling costs are subject to considerable economies of size, which also depend on the power plant.

Farm Level Costs

The removal of crop residue has possible adverse agronomic effects from reduced organic matter and moisture retention capacity, increased susceptibility to erosion, and the lost fertilizer value of the plant material. While organic matter generally is recognized as a valuable soil amendment, there is not a clear relationship between crop residue removal and yields. Adams, Morris, and Dawson found that stalk removal had no effect on yields for continuous corn with and without a cover crop or for corn grown in rotation. Triplett and Mannering conclude that nonlegume crop residues seem to have little value except in erosion control. Bauer actually found that adding residues had either no effect or a slightly depressing impact on yields. Thus, it is assumed that no yield penalty or other cost is incurred as residue is removed. Substantial costs are incurred because of the loss of the fertilizer value of the residues removed. Additional amounts of the major plant nutrients—nitrogen, phosphorus, and potassium—have to be applied to maintain yields. When residues are incorporated into the soil, not all of the nutrients become available to next year's crop. Residues decay over long periods of time, releasing only a fraction of the nutrients in any year. To estimate the value of these residues, a decay schedule is used to estimate the discounted present value of the flow of nutrients. Broadbent, in a literature review on the mineralization of organic nitrogen, found a range of decay rates from less than 1.0% to 10%. It is assumed that the decay rate for nitrogen and phosphorus is 5%. Potassium is not discounted because it is readily washed out of crop residues and becomes readily available to the succeeding crop.[3] The net dis-

[2] This constraint insures that aftermath demands assumed in the exogenous livestock rations will be met. This was done to develop a model reflecting current uses. It is true that once crop residues have a market demand, then this quantity would vary. No attempt is made here to estimate this.

[3] Personal communication with W. D. Shrader, Department of Agronomy, Iowa State University, August 1977.

counted fertilizer value, or the opportunity cost of fertilizer, is shown in table 1.

Many studies have been made of the costs of harvesting plant materials using a variety of harvesting systems. Five basic packaging systems are examined: (*a*) small rectangular bales, (*b*) cubing, (*c*) large rectangular bales, (*d*) large round bales, and (*e*) stacks. The first two systems are not economically viable. While costs of large round and rectangular bales are competitive, difficulties are foreseen in handling and storing these residues. Large stacks have several advantages over other systems in residue harvesting. The stack can be placed at the roadside without protection since stack deterioration is less than would occur with other harvesting systems. Truck mounted stack-movers have been developed to facilitate transfer. Finally, assuming windrowing would not be necessary and that 1,000 tons are harvested per year per stack harvester, they are the least costly. This finding concurs with those of Abdullah and Hitzhusen.

Transportation Costs

Transportation costs are a small but an important portion of total costs. They are an increasing function of transportation distance, so a series of costs is estimated for a range of average round-trip distances.[4] The average round-trip distance depends on the size and shape of the collection area which, in turn, depends on the total quantity of crop residues demanded, the density of crop residue within the area, the demand for residues by competing uses, and the proportion of farmers harvesting residues. The collection areas for crop residues reflect an assumed 25% participation rate, as recommended by Shrader. Although this increases transportation costs, we think this assumption is necessary to make the model realistic.

In most of the Midwest, the road system is an east-west, north-south grid. The loci of points equidistant from each power plant form a diamond shaped area. A marginal transportation distance is selected so that the amount of available residues is equal to that required by the power plant. Assuming that crop residues on a given section of land are harvested once every four years and livestock residue feed demands are met, the average transportation distance is two-thirds the marginal or perimeter distance.[5] Per ton transportation costs, including loading and unloading costs, are \$0.76, \$0.95, \$1.05, \$1.20, \$1.50, and \$2.00 for round trip distances at 4, 10, 15, 20, 30, and 50 miles, respectively (English et al.).

Processing Costs

Costs of processing crop residues are estimated from hypothetical processing plants. Facilities do not now exist that are designed and built to prepare crop residue for energy conversion. Like a solid waste treatment plant, the flow line of the hypothetical processing plant has four main elements.[6] Modifications for introducing crop residues into the boilers are included in these costs. Estimates of processing and handling costs show considerable economies of size (table 2).

Capital costs, in 1978 dollars, are annualized using a capital recovery factor with a 10% discount rate and a square type depreciation schedule (Smith).[7] The processing equipment is assumed to have a useful life of twenty years, while a six-year life span is assumed for the pneumatic system. Salvage values are assumed equal to dismantling costs. The costs of

Table 1. Discounted Present Value of Nutrients per Ton of Crop Residue Removed by Crop

	Fertilizer value[a] of			
Crop	Nitrogen	Phosphorous	Potassium	Total Value
	(\$/ton)			
Corn	1.39	0.32	2.67	4.38
Oats	0.75	0.31	3.32	4.38
Sorghum	1.35	0.24	2.63	4.22
Soybeans	2.88	0.38	2.08	5.34
Wheat	0.76	0.10	1.93	2.79

[a] Present value calculated in 1975 dollars using a 10% discount rate and prices of 18¢, 26¢, and 10¢ per pound for nitrogens, phosphorus, and potassium, respectively.

[4] Using expected round trip distances has implications for the institutional arrangements by which crop residues are collected. If each farmer were to deliver his own residue and the power plants are not discriminating monopolists, then the marginal distance should be used.

[5] The expected distance is determined from $\int_0^r \int_0^{r-x} (x + y)\,(2/r^2)\,dydx = 2/3r$, where a coordinate system in x and y is used. $x + y$ is the transportation distance, r is the perimeter distance, and $2/r^2 = f_{x,y}(x,y)$ is the probability density function for a random selection from anywhere within the perimeter.

[6] The four main elements include the tipping floor where residues are received, the size reduction equipment (assumed to be a hog, as used in the forest industry) which reduces residues to a homogenous size, storage facilities, and, finally, boiler modifications to permit residue burning. Conveyors are needed between the main elements.

[7] These costs were developed with the help of Harvey Funk and Dan Morriouri of Henningson, Durham, and Richardson, Omaha, Nebraska.

Table 2. Capital Costs for Crop Residue Processing and Handling Plants

Item	Processing Plant Capacity in Tons per Day				
	100	300	600	900	1200
	($ thou.)				
Sitework	112.4	135.6	145.7	153.7	160.1
Buildings	168.6	368.7	673.2	1,016.0	1,377.9
Equipment	666.4	951.7	1,150.8	1,390.7	1,532.3
Rolling stock	38.1	51.4	95.8	95.8	95.8

Pneumatic system	154.3	154.3	154.3	154.3	154.3
Total	1,388.9	1,992.3	2,670.0	3,397.4	4,010.2

the pneumatic system and for the modification of existing boilers were those incurred at Ames, Iowa, in adapting to municipal solid wastes (Kosolchareon). While individual capital cost components may differ, the total capital costs are similar to Abdullah and Hitzhusen. For a 100-ton-per-day crop residue-processing facility, the capital costs assumed here are $1.39 million compared to Abdullah and Hitzhusen's estimate of $1.43 million. The economies of size in processing and handling crop residues outweigh diseconomies of size in transportation. This indicates that the lowest total costs for crop residues will be incurred by the larger power plants (table 3).

Results

Crop residue use affects crop production, energy consumed, nitrogen demanded, agricultural production cost, and net income. The impacts of utilizing crop residues on Iowa's agricultural sector are first examined, then the economic viability of using crop residues are determined by examining the costs and benefits of residue use compared to coal use.

Table 3. Total Costs of Crop Residues to the Power Plant

Cost Stage	Processing Plant Capacity in Tons per Year				
	24,800	74,400	148,800	223,200	297,600
	($/ton)				
Farm level	11.68	11.68	11.68	11.68	11.68
Transportation	.79	.91	.99	1.05	1.11
Processing and handling[a]	12.66	6.11	4.28	3.63	3.22
Total	25.13	18.70	16.95	16.36	16.01

[a] Includes capital costs, operating and maintenance costs, and labor costs.

As energy prices increase, total changes in energy use, measured in Btu's, do not vary significantly from one scenario to another. However, energy use by the agricultural sector increases with removal of crop residues. Energy use from conventional fuel sources (other than coal) increases with the substitution of crop residues. This increase is far less than the coal energy replaced by residues (table 4). Thus, the use of crop residues results in a large reduction in total energy from coal and a small increase in the use of diesel, natural gas, electricity, and liquid petroleum gas.

Impacts on Iowa's Agricultural Sector

The total value of endogenous crops exceeds $3 billion in all scenarios examined. The ag-

[a] Liquid petroleum gas.

ricultural sector is affected by increased energy prices and by the amount of residues harvested for the power plants but is, of course, unaffected by reduced sulfur emissions; the gross value of crops produced is identical for both the Increased Energy Prices and Reduced Sulfur Emissions scenarios. The gross value of crops produced is 1.78% lower in these scenarios than the base scenario with no coal replacement (table 5). As the percentage of coal replaced with crop residues rises to 60%, the gross value of crops produced decreases to 0.54% of the value produced in the Base Scenario. This shift is for the most part caused by a shift from soybean to corn production, a higher residue-yielding crop.

Nitrogen use decreases between 8.5% to 9% at all levels of crop residues as energy prices increase. The harvesting of crop residues results in additional nitrogen requirements of 10, 20, and 30 thousand tons to replace the nitrogen used in crop production as cropping patterns change. More nitrogen-intensive rotations are required as residue demand increases.

Several components must be examined before net income is derived. As previously mentioned, the objective function includes not only the costs and returns attributed to agricultural production, but also the minehead costs, transportation and handling costs of coal used by Iowa's power plants, and the transportation and processing costs of crop residues. When these components are added to the objective function, net income to the crop and crop residue-producing portion of the agriculture sector is derived. Net income then is the monetary return to Iowa farmers, but does not reflect any cost for land, management, or the risk aspects of agriculture (table 6). As 20%, 40%, and 60% levels of crop residue use are assumed, a respective decrease in net income of 1.36%, 2.81%, and 4.17% occurs in the Base scenario. Thus, the farmers must receive at least this amount as a return on labor and capital used before residues will be provided to the power plants.

Table 5. Gross Value of Crops Marketed and Percentage Changes between and within the Scenarios

Percentage of Coal Replaced	Value of Crops for: Base Scenario	Increased Energy Prices	Reduced Sulfur Emission
	($ mill.)		
0	3,461.5	3,399.9	3,399.9
20	3,467.4	3,404.6	3,404.6
40	3,475.1	3,383.7	3,383.7
60	3,483.3	3,381.6	3,381.6

As energy prices increase and sulfur levels are further restricted, the net income decrease is much less. This loss in net income is due primarily to the agronomic and harvestings costs borne by the farmer. An additional cost is incurred because of shifting crop patterns.

Economic Feasibility of Crop Residues

The costs of crop residues include both direct and indirect costs (table 6). The direct costs are those attributed to harvesting, transporting, and processing the residues plus the agronomic costs of nutrient replacement. The indirect costs include those due to cropping pattern shifts caused when residues are supplied by farmers. Other costs of crop residues, such as organic matter maintenance and decreased productivity over the long run, and benefits, such as reduced pesticide use and reduced fall plowing, are not incorporated within the scope of the study. These components would affect the indirect costs of crop residue.

On a Btu basis alone, the use of crop residues becomes economically feasible only when coal and other energy prices double from approximately 1977 levels (table 7). Even at this point, the feasibility of residues is marginal. If the benefit of the sulfur contribution is credited, however, the doubled coal and energy price scenario indicates crop residues are indeed feasible with a net benefit of $0.25 and $0.43 per million Btus (MMBtu) for the 20% and 60% levels, respectively. If sulfur emissions are further constrained, this added benefit increases to $0.36 and $0.49 per MMBtu. This last scenario is perhaps most relevant because power plants usually meet legal constraints by a wide margin.[8]

The costs incurred by farmers and the power plant operators are shown in figure 2. These results are consistent over all the scenarios, though the percentages differ slightly because of increased energy costs. The figure shows that the farmer's share of the

costs increases as the percentage of residue used increases. This increase is primarily due to the fixed costs inherent in the power plant's processing facility, a large capital investment.

This analysis does not include any costs associated with risk. In addition, the hypothetical processing plant may not be optimum in the real world. Additional benefits received by farmers for their residue harvesting efforts, including reduced fall plowing and reduced need for pesticides and herbicides, are not incorporated into the analysis. These benefits could allow the power plant to pay less to

Table 7. Economic Feasibility of Crop Residues When Evaluated on a Btu Basis Alone

Type of Fuel by Scenario	Percentage BTU Replacement of Residue for Coal at 20	40	60
	($/MMBtu)

[a] Negative quantities indicate lower costs for coal, while positive figures show lower costs for residues.

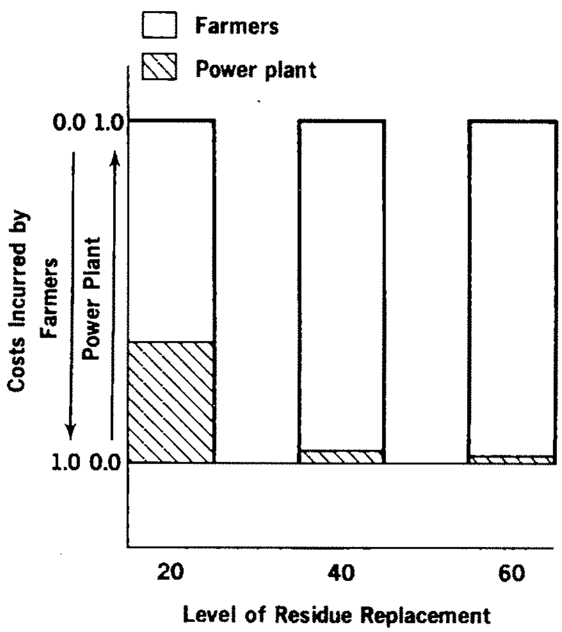

Figure 2. Proportion of costs incurred by the farmers and power plant operators

farmers than otherwise. Recall that the 60% replacement level is not currently feasible for all power plants. The economics for a particular power plant must be examined on an individual basis, as was done for two power plants by Abdullah and Hitzhusen.

The results of this study suggest that under the rapid upward trend in energy prices, the use of crop residues may indeed be feasible. This development could permit a large reduction in low-sulfur coal use for a small increase in other conventional energy sources.

While this study indicates that residues are a feasible feed stock for electrical generation, several parameters should be examined in a more detailed manner. These parameters include the farmers' willingness to harvest residues, the farmers' opportunity cost, and estimates of actual plant capacity for stover combustion. Each of these variables is local in nature as they will change from one power plant to another. Before recommending that power plants incorporate residue as a feed stock, a study of area farmer attitudes toward residue harvesting and storing should be conducted.

Agricultural Export Dumping: The Case of Mexican Winter Vegetables in the U.S. Market

Andrew Schmitz, Robert S. Firch, and Jimmye S. Hillman

This paper examines the 1978 agricultural dumping charge brought by Florida winter vegetable producers against Mexican growers. It discusses "fair value" in the context of three antidumping criteria: prices at home and abroad, selling below cost of production, and third-market test. The U.S. Department of Commerce found in favor of the Mexican producers by using the third-market test—a test which leads to ambiguous results. It is the authors' contention that the law should be changed so that future cases can be decided on a "normal business practice" concept, accounting for production and costing decisions unique to highly perishable products.

Key words: agricultural dumping, fair value, normal business practice.

Among international trade economists, the term "dumping" usually refers to cases where the good is either exported abroad at a price below that set in the home market or it is sold to importers at a price below production costs. Most of the theory and legal cases have involved manufactured goods. The antidumping case examined in this paper deals with highly perishable agricultural products. The case is the October 1978 dumping charge brought by Florida winter vegetable producers against Mexican growers. Because of climatic conditions, Florida is the only major geographic area in the United States that can produce substantial volumes of fresh vegetables during the winter months. These vegetables are marketed in the United States and Canada. Competing for these markets with Florida producers are Mexican growers situated in the state of Sinaloa. Slightly more than half of the tomatoes, cucumbers, peppers, eggplants, and squash sold in the United States and Canada in the winter months come from Mexico.[1] Of the five major items considered (tomatoes, cucumbers, peppers, eggplants, and squash), Mexico's market share increased through much of the early part of the period considered, at the expense of Florida's share, even though Florida's absolute production level increased.

In contrast to manufactured goods, dumping investigations for perishable agricultural commodities have been rare. During 1976, twelve antidumping investigations were concluded, but no agricultural products were involved. However, there were some agricultural antidumping cases in other years, for example, Concord grapes from Canada (1969) and chicken eggs from Mexico (1971) and from Canada (1975). However, the U.S. Treasury Department, in investigating the complaint by the Florida vegetable industry against Mexican producers, did not use the approaches established in these cases; apparently they provided little or no precedent for appropriate methods to be used.

The antidumping investigation was initiated by the U.S. Treasury Department under the provisions of the Antidumping Act of 1921, as amended. The Act requires a Tentative De-

[1] Excellent data from which to make comparisons between the Florida and Mexican vegetable industries are contained in McCalla and King; Simmons, Pearson, and Smith; and Zepp and Simmons (1979, 1980). In addition to general production and marketing trends unfavorable to Florida growers, short-term phenomena have permitted increases in Mexican vegetable exports. These include the Florida winter freeze in the 1976–77 crop year and the devaluation of the Mexican peso in 1976.

termination to be announced after a specified period of time. However, Florida interests withdrew their petition on 25 July 1979. Several agencies of the U.S. government had requested the withdrawal of the petition in the hope that a resolution could be negotiated and Mexican interests would agree to restrict their shipments to the U.S. market under special circumstances. Such a solution would have precluded further action under the Antidumping Act. Efforts to negotiate a settlement failed, and on 19 October 1979 the petition was refiled. The Tentative Determination (5 November 1979) found that certain fresh winter vegetables from Mexico were not being sold at less than fair value within the meaning of the Act.

On 1 January 1980, the antidumping provisions of the Trade Agreements Act of 1979, which amended the Tariff Act of 1930, became effective. The Antidumping Act of 1921 was repealed, and the responsibility for dumping determinations was transferred to the U.S. Department of Commerce. The transition rules in the 1979 act were sufficiently vague so that the Department of Commerce first ruled that the antidumping investigation of Mexican vegetables had been automatically terminated at the transition date. Later it ruled that continuation of the investigation was consistent with the intent of Congress. The Final Determination became effective on 28 March 1980. The summary statement of findings, "that certain fresh winter vegetables from Mexico are not being sold at less than fair value within the meaning of Section 735 of the Tariff Act of 1930, as amended" (U.S. Department of Commerce, p. 1), was virtually identical with that of the Tentative Determination.

In this paper, we discuss three dumping criteria which have been used to determine "fair value": (*a*) comparing prices at home and abroad, (*b*) selling below cost of production, and (*c*) comparing prices in two or more import markets (the third-country test). We show the inconsistencies which can arise among these various tests and how the concept of fair value permits a wide scope for analytical techniques and judgment in case analysis. The outcome of the Mexican-Florida lawsuit is then discussed in the context of both law and economics. We argue that the law should be changed so that economic analysis can play a more effective role in determining fair value in dumping cases. Specifically, we contend that the final decision by the U.S. Department of Commerce should have been based, at least in part, on a cost-of-production criterion to reflect both the nature of agricultural production and normal business practices. Instead, the Department used the third-market test (i.e., comparing U.S. and Canadian prices for vegetables from Mexico). This is because a cost-of-production test, as it is now written into the law, cannot be applied to most agricultural goods.

This case is important for several reasons. First, the outcome was unpredictable because of the relatively unconstrained method of investigation. Most substantive dumping cases have been in manufactured goods. In these cases, either or both of the following criteria have been used: (*a*) selling abroad at a price below that charged at home and (*b*) selling abroad at a price below the cost of production. The agricultural dumping case discussed in this paper is somewhat unique because (*a*) an agricultural good is considered for which there is little legal precedent; (*b*) the cost of production has a different meaning for agricultural than manufactured goods because of the importance of weather, storage problems, and implicit pricing of land and family labor; and (*c*) in this case, there is no home (Mexican) market. Second, the methods used to investigate the dumping of Mexican vegetables may establish important precedents for future dumping investigations of other perishable commodities. Third, the finding of no dumping in this case may discourage other U.S. producers of perishables from pursuing dumping investigations of foreign competitors.

The Theory of Dumping and Tests Used in Antidumping Investigations

Generally, dumping is understood to mean that a product is exported at a price lower than that at which the identical or similar product is sold by the same producers in the exporting country's domestic market (Corden). This subject has received much attention in the commercial policies and tariff legislation of most countries. Also, there is a General Agreement on Tariffs and Trade (GATT) Antidumping Code which, in certain cases, legitimizes antidumping tariffs.

An extreme case of dumping is shown in figure 1. Suppose the supply schedule for export producers is S and marketing is carried out by an exporter-grower association which has monopoly power. The demand in the ex-

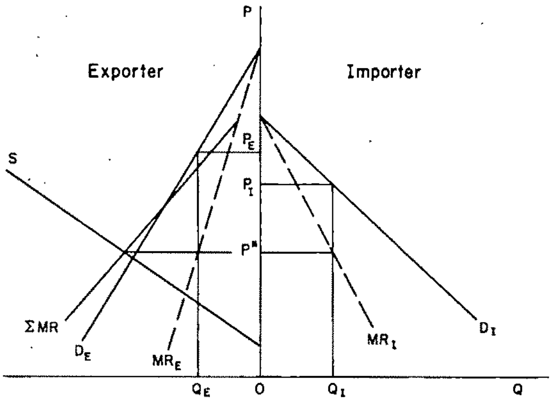

Figure 1. Export dumping: importer price below home market price

porting country (domestic market) is D_E, while D_I is the demand in the foreign market. Under an optimal price strategy, the exporter will charge price P_E in the domestic market and P_I in the foreign market, which is below the domestic price. (This solution is determined by equating S with the sum of the marginal revenue schedules, MR_I and MR_E.) Pricing in this way is dumping. However, to price in this manner, the exporter has to be a monopolist.

The case examined here is more interesting than many antidumping investigations in manufactured goods because the important criterion used in antidumping cases—selling abroad at a price below that in the home market—could not be used. Fresh winter vegetables produced in Sinaloa, Mexico, are produced with the sole intent of sale for export. Except for an insignificant amount, exporters sell into the Mexican market only those vegetables that fail to meet the high-quality standards for export to the United States and Canada. Geography and transportation costs exclude Sinaloa from profitable sales in the population centers of Mexico. In effect, similar merchandise is not sold in the home market.

Sometimes dumping is described as exporting below the costs of production. In figure 1, if this criterion had been used instead of the relative prices among markets, no dumping would have occurred. The cost of producing Q_E + Q_I is only P^*, clearly below both the domestic and export prices. As a result, the conclusion whether or not dumping has occurred is dependent on the criterion used. As figure 1 shows, if an industry behaves as a monopolist, dumping does not occur if the selling below-cost criterion is used. But it does occur if the criterion of selling abroad cheaper than at home is employed.

With perishable agricultural products, the criterion of selling below cost of production reflects a different meaning than for manufactured goods. Unfortunately, as the law now stands, no distinction is made between the two. On economic grounds, this makes little sense. Weather plays a major role in the production of farm products; hence, outcomes are not known at the time the crops are planted. At harvesttime, a grower may not be able to sell his product at a price high enough to cover both fixed and variable costs; yet, he may decide to harvest and sell the crop if the price will cover harvesting costs.

Later it will become clear why, if the Department of Commerce wanted to rule in Mexico's favor, it did not use the cost-of-production test. Instead, the Treasury Department argued that, since the first criterion could not be used, a price comparison should be made between Canada and the United States and, if the prices were similar, the antidumping case could not be supported. This criterion is illustrated in figure 2. The export supply is S, but the domestic demand is absent. There are two importers represented by demand D and the total demand schedule, TD. Under purely competitive conditions, the exporter would receive P^* in both markets. Because domestic demand is absent, the most widely used criterion of comparing prices at home and abroad is inappropriate for determining if dumping is occurring. Clearly, dumping is not taking place if the price charged in both markets is P^*. However, does this test lead to results consistent with the other widely used criteria? Also, does it show that dumping is not, in fact, occurring? One problem

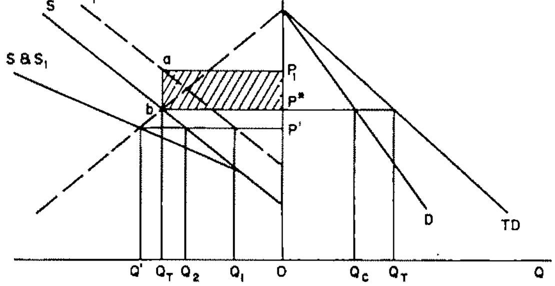

Figure 2. Export dumping: the use of the third market test

with the third-country test is that it can lead to results inconsistent with the costs-of-production criterion. Suppose that the true supply curve is S_1 instead of S in figure 2. In this case, the price needed to cover the cost of producing Q_T is P_1. If sales are made at P^*, area P_1abP^* must be made up from past profits, government subsidies, or a depletion of fixed capital. Here the exporter charges the same price, P^*, to the two importers. This is not dumping under the third-market criterion, but it is under the criterion of selling below cost. As a result, it does not necessarily follow that the third-country criterion leads to results consistent with the more commonly used criterion—selling below the costs of production. Even if the third-market test were met (i.e., P^* was charged in both markets ignoring transportation costs) virtually no conclusions can be drawn about dumping. If S_1 is the supply curve and price P^* is charged, then dumping exists. If, on the other hand, S is the supply curve, dumping does not occur. If the third-market test is met, one can say that either dumping has occurred in both markets or it has occurred in neither. That is all.

The third-market test to determine fair value seems to have as its basis the model in figure 1, where D_E and D_I are now demand curves for importers (the home market demand is absent) and S is the exporter supply curve. In the Florida-Mexican case, if D_I were the demand in the United States and D_E the demand in Canada, dumping would have occurred in the U.S. market at price P_I. In the absence of subsidies in the export countries, dumping is occurring even when the exporter is making excess profits in both markets through price discrimination. These results are modified only slightly when a supply curve is introduced in the import market.

Dumping should not be confused with phenomena caused by differences in production costs. If producers in an importing country continue to lose their market share through time even when competing imports are not subsidized, dumping is probably not occurring since export producers cannot sell below production costs forever. Consider figure 2, where TD is the demand by the United States and Canada for fresh vegetables. Assume that S is the supply in Mexico and S_I is the supply of fresh vegetables in the United States. The difference in these supply curves could be due, for example, to labor costs differences. The free market price is P'; OQ^2 of the market is supplied by Mexico and only OQ_1 by the United States. If the difference between S and S_1 widens and is not offset by tariffs, then the U.S. market share will continue to decline. This is not because of dumping—it is caused by factors which make vegetable production cheaper in Mexico than in the United States. On the other hand, if the distance between the two supply curves narrows through time, it is again difficult to argue that dumping is occurring. How does one dump effectively and still lose market share through time?

The Interplay of Law and Economics

For antidumping investigations, the law establishes this basic premise: Generally, sales at less than fair value occur when merchandise exported to the United States is sold in the United States at a price which is less than (*a*) the price of such or similar merchandise sold in the home market; (*b*) in the absence of a viable home market, the price at which it is sold in the third country; or (*c*) the constructed value. The latter closely resembles the cost-of-production criterion discussed earlier. The preeminent concept in dumping investigations and their determination is clearly fair value. It was certainly the intent of the Congress to give broad latitude to the investigating agency to define fair value and attendant procedures. This is surely a reflection of a recognition that the characteristics of production, marketing, and pricing vary a great deal from one commodity to another and the impossibility of anticipating the peculiar characteristics of any one commodity that might become the subject of a future investigation. An important corollary of the concept of fair value is that its definition should be consistent with normal business practice so that marketing and pricing practices considered "normal" for a particular commodity would not lead to a dumping finding.

Normal Business Practice for Perishable Agricultural Products

An understanding of the economics of production, marketing, and pricing of fresh vegetable commodities and the willingness to let this be reflected fully through the normal business practice doctrine was crucial in the Final Determination that Mexican vegetables had not been dumped in the U.S. market. If a substantially lesser role was given to economics—

and, therefore, a larger role for a literal application of the law—a finding of dumping most likely would have resulted.

The distinction between fixed and variable costs has important significance for highly perishable agricultural commodities. Because it is basically a biological process, agricultural production, once initiated, is largely beyond the control of the farmer. Maturity of the product means that the farmer has from a few weeks to a few hours, depending upon the commodity, to harvest it or suffer rapid deterioration in its economic value. The fresh vegetables at issue here can be harvested any week of the year somewhere in North America. Because of this continuous production, high storage costs relative to the value of the product, and the deterioration of the product when stored, it is not feasible to store fresh vegetables for more than a day or two. Under these circumstances, when the commodity is mature enough for normal harvest, the rational farmer looks at the prevailing price for the product; and if that price exceeds the variable harvesting and transfer costs, he must harvest and sell the product. Following this course, the farmer usually will recover all of his variable costs and at least a part of his fixed costs. Always waiting for a price that covers full costs of production will increase the likelihood of bankruptcy rather than continued survival of the firm.

Of all fresh vegetables and melons sold by U.S. farmers in 1977, potatoes ranked first in total value, lettuce ranked second, and tomatoes ranked third. Potatoes are relatively storable compared to lettuce and tomatoes, which can be stored for only a few days. Table 1 vividly illustrates that sales below full cost were common for California lettuce and Florida tomato growers over the ten-year period, 1968–78. The two California lettuce-producing districts are the largest in the United States. Florida's riper tomatoes are produced on stakes and trellises, to be harvested at a more advanced level of maturity. Florida's green tomatoes are grown without supporting devices and must be harvested in less mature condition.

Table 1 shows clearly that farmers do commonly harvest and sell their products at prices below full costs. Florida growers might say that the only reason for doing this is Mexican producers damage their markets. This explanation has little credence because below-cost sales are much more common for California lettuce, which has no Mexican competition in the U.S. or Canadian markets. It is also true that a higher proportion of Mexican tomato sales are riper tomatoes than is the case with Florida. Of the four combinations of area and commodity reported in the table, the one having the most direct and persistent competition from Mexico also has the lowest incidence of below-cost sales.

Table 2 shows that failure to recover full cost is common not only for week-long periods but also for entire production seasons and is independent of competition from Mexico. At the end of each production season, University of Florida researchers interview Florida vegetable producers to estimate total costs and sales revenues for each of the principal commodities. They treat the two types of tomato production separately. These two types of tomatoes and the other four vegetables (cucum-

Table 1. A Comparison of the Occurrence of Below-Full-Cost Sales of Tomatoes and Lettuce during 1968–78

Commodity	Total Weeks of Data	Total Weeks with Some Sales below Full Cost	Total Weeks with All Sales below Full Cost
		(%)	(%)

bers, peppers, eggplants, and squash) are six commodities that compete with the controversial Mexican trade. For purposes of comparison, the six vegetables (lettuce, sweet corn, celery, potatoes, cabbage, and radishes) with the highest sales value but no Mexican competition were also studied (table 2).

The costs included in table 2 do not include management or capital costs in this very risky business activity. Therefore, in about one year out of four, Florida vegetable growers received no payment for their management skills and risks and also failed to cover other costs. There does not seem to be any significant difference in the frequency of net losses between the two groups of commodities. Tomatoes have both higher costs and higher sales revenue per acre. This largely explains the higher net returns per acre for the six commodities with Mexican competition. The average percentage of return is slightly lower for the commodities with Mexican competition, but these commodities have substantially lower variability of returns. Economic theory and observation strongly suggest that low average returns normally correlate with low variability of returns. The fact that standard deviations are larger than the average values indicates great profit variability and the relatively high probability of net losses in any given year.

Application of Tests for the Existence of Dumping

In the antidumping case examined here, the U.S. Treasury and Commerce Departments realized that the common test (i.e., foreign merchandise sold in the United States at a price below that of similar merchandise sold in the home market) could not be applied because the Mexican vegetables are produced with the sole intent of export. Thus, the Treasury and Commerce Departments chose to apply the third-country test rather than the constructed value (cost of production) test. The method used in applying the third-country test seems to satisfy the mandate of the law, but the economic interpretation of the findings can be judged only as ambiguous. That is, even though it was shown statistically that prices in Canada for fresh vegetables behave similarly to those in the United States, it cannot be inferred (without additional evidence) that dumping has not occurred.

A general observation of the market for fresh vegetables functioning at Nogales, Arizona (the U.S. port of entry for Mexican vegetables) suggests that there is no purely economic discrimination between U.S. and Canadian buyers. Brokers in Nogales representing Mexican growers try to get the highest possible price because their income is a direct function of sale price. Salaried buyers and brokers representing buyers in the United States and Canada work to get the lowest price they can for any given quality. With many buyers and sellers operating in this market, it is impossible for any systematic price differences between U.S. and Canadian buyers to exist after the effects of other relevant economic variables have been considered. In addition, it is difficult to imagine that price elas-

ticities for the commodities would be different between Canada and the United States. As figure 1 shows, differing price elasticities must exist for successful dumping to occur if subsidies are not given by the exporting country. Identical or similar per capita demand curves do not yield a price discrimination solution.

A crucial issue in applying the third-country test was whether actual below-cost sales should or could be included in the analysis. Exclusion of below-cost sales would reduce the number of available observations on Canadian sales, thereby jeopardizing the legitimacy of the third-country test. Excluding below-cost sales might also raise daily prices to Canadian buyers relative to prices to U.S. buyers, thereby increasing the probability that statistical tests would find significantly different prices in the U.S. and Canadian markets.

In its Final Determination, the government chose to confront this problem as follows:

> These standards would not require the disregarding of below-cost sales in every instance, for under normal business practice in both foreign countries and the United States, it is frequently necessary to sell obsolete or end-of-model year merchandise at less than cost. . . . Thus, infrequent sales at less than cost, or sales at prices which will permit recovery of all costs based on anticipated sales volume over a reasonable period of time would not be disregarded. . . . (U.S. Department of Commerce, p. 16)

The Commerce Department thus found ample basis for applying the normal business practice doctrine. This is consistent with the discussion in the previous section of this paper. Counsel for the Mexican interests submitted substantial material arguing that below-cost sales were a common and persistent practice, while counsel representing the Florida interests made no submissions on this issue even though, as shown, the same phenomenon occurs in the United States.

In its Final Determination, the Commerce Department stated: "The conclusion that there is no price discrimination between the U.S. and Canadian markets was tested by means of an F-test on regression analysis" (p. 19). It reiterated: "The results of the F-test performed on the regression show conclusively that there is no discrimination in the pricing of fresh winter vegetables sold in the U.S. compared with those sold in Canada" (p. 19). The Commerce Department gave further support for its conclusions by stating:

> Further, given the clear statistical evidence of the unitary nature of the markets and the absence of any barriers to the free flow of this merchandise across the U.S.-Canadian border, any sustained price discrimination in favor of U.S. buyers almost certainly would result in arbitrage (the reselling of merchandise by a U.S. buyer to a Canadian buyer for a profit). There is no evidence that any such practice occurs. (p. 19)

While the government may have amply demonstrated that the Mexican produce is sold at the same price to U.S. and Canadian buyers, thus fully satisfying the language of the law, two different economic conclusions are possible because Florida producers also supply about half of the Canadian purchases of fresh winter vegetables. On purely economic grounds, one could conclude that there is either no Mexican dumping in U.S. or Canadian markets or that there is dumping in both. The Final Determination does not provide the basis for determining which conclusion is correct. This casts doubt on the validity of the third-country test, especially when the United States is a substantial exporter to the same third country.

The cost-of-production test for the existence of dumping requires, in effect, that each sale price exceed the constructed value. The law and precedents of previous findings allow the constructed value to be only the full cost of production plus 8%. If this criterion had been used here, Mexico would have been found guilty of dumping. However, it is clearly a normal business practice for both Florida and Mexico producers to sell below full cost of production plus 8%.

The Commerce Department in its Final Determination stated that

> use of constructed value is not required by the 1979 Act, . . . expresses a general preference for the use of third country sales, rather than constructed value, where home market prices cannot be used. Furthermore, use of constructed value in this case would produce a result that manifestly disregards economic reality. . . . The use of a unitary price, such as constructed value, in circumstances such as those presented by this case would necessarily result in less than fair value sales even though sellers are acting in a normal, indeed in a necessary, way given the nature of the industry. Thus, use of constructed value would be inappropriate because it would require finding that an accepted, reasonable and economically necessary practice is unfair. (p. 22)

Because the Commerce Department apparently saw insufficient latitude to apply the normal business practice doctrine within the constructed value test, a conclusion reasonable on economic grounds could not be

reached. It then used a normal business practice argument to justify not using the constructed value test.

In the vegetable antidumping case, it is clear that, unless the Mexican government provides export subsidies and/or production subsidies, it is impossible for growers to sell continuously below cost.[2] Growers cannot use profits from domestic sales to support such an activity.

Other Available Data

To provide additional evidence on the dumping question, a regression trend analysis was applied to shipments of each of the five vegetables—tomatoes, peppers, cucumbers, squash, and eggplant—for every consecutive ten-year period from 1962–63 through the 1978–79 season. The results in table 3 provide insight into the relative success of the Florida and Mexico fresh winter vegetable industries in competing for the U.S. and Canadian markets over the seventeen seasons ending with the 1978–79 season. The interpretation of table 3 is, for example, that the total sales of tomatoes—from all sources during the winter season—increased at an average rate of 753,400 thirty-pound cartons per year during the period beginning with the fall of 1962 and ending with the spring of 1972. The asterisk following the 753.4 figure indicates a very low probability that the annual increase is really zero. A very high level of statistical reliability is associated with the measured trend.

The data show that the trend in total sales for each of the five vegetables has been positive throughout the period studied. Therefore, the competition between Florida and Mexico has occurred within an expanding total market. The competition would be much more severe if the total quantity absorbed by the market were either static or declining over time.[3] In addition, the trend values show clearly that the total quantity absorbed by the market for each of the five vegetables has not only been increasing over this seventeen-year period but has been increasing at an increasing rate. Over the 1969–79 period, the annual growth of combined Florida and Mexico shipments has increased at an annual rate of 4.2% for tomatoes, 7.8% for peppers, 5.9% for cucumbers, 13.4% for squash, and 7.3% for eggplant. These rates are substantial when compared with the growth in real U.S. total disposable income of 2.9% during the same period. Per capita consumption of most fresh fruits and vegetables produced in the United States has declined since 1950.

Consider the period 1969–79. Shipments of tomatoes, peppers, and eggplant from Florida increased substantially more than the respective shipments from Mexico. Cucumber shipments from Mexico increased slightly more than shipments from Florida, and shipments of squash from Mexico increased more than 40% over shipments from Florida. (Based on the total value of Florida's shipments of the five vegetables for the 1977–78 season, cucumbers represented less than 9% and squash less than 3% of the total.) Florida achieved this dominant competitive position in the third era despite unusually damaging cold weather during 1976–77 and 1977–78. On a total product weight basis, Florida captured 65% of the total market growth in the 1969–79 period. Shipment data for 1962–79 show clearly that, in the early part of this period, Mexico had a strong advantage which it effectively exploited as its industry rapidly expanded and Florida's declined. Toward the end of the 1962–79 period, however, Florida's shipments increased much more rapidly than Mexico's. Florida has been competing effectively with Mexico in recent years. To sustain dumping allegations in this relatively free market clearly would be inconsistent with the current competitive situation.

Conclusions

As this paper shows, the application of the antidumping laws to highly perishable commodities, such as fresh vegetables, presents formidable problems of economic analysis. The third-country test, as applied in this case, can lead to ambiguous results. The constructed value, or cost-of-production, test may lead to a finding of dumping even when foreign producers behave in a manner identical to U.S. producers whether or not import compe-

[2] The brief prepared for the Florida vegetable industry contended that excess profits were made by the Mexican producers during periods when the Florida producers had no, or very few, products for sale. Since this happened only during the freeze period, the increased earnings by Mexico are not excess profits resulting from a permanent monopoly.

[3] An examination of quantity data reveals that reported shipments by sources other than Florida and Mexico increased by extremely large proportions during the 1975–76 season for cucumbers and the 1976–77 season for tomatoes, peppers, and squash. In order to circumvent possible distortions in shipment data from other areas, trends were measured on only the combined shipments of Florida and Mexico.

[a] Figures in parentheses indicate the percentage of probability that the number immediately preceding it is not significantly different from zero; probability less than 0.05%.

[b] Asterisk indicates that the annual increase is not significantly different from zero.

[c] Total shipments of cucumbers for the 1967–68 season were adjusted because the published data showed the sum of Florida and Mexico to be more than total shipments. The adjustment assumed that areas other than Florida and Mexico shipped a quantity in 1967–68 that was on a linear trend of the 1962–72 period.

tition is present. It seems clear that the Congress did not intend for the latter to occur.

What are the appropriate solutions to this apparent incompatability of the law and economics? The law should be changed. Either perishable agricultural commodities should be exempted from the law or the law should be changed to allow the application of more sophisticated economic and statistical analyses. The models used should have the capability to distinguish between normal and abnormal behavior of foreign producers, the behavior of U.S. producers being standard. In the current law, exporters of perishable agricultural products have a difficult time defending themselves in antidumping suits if the cost-of-production criterion is used to determine fair market value. A normal business practice concept should be explicitly incorporated into law for perishable agricultural products. Supporting this concept indirectly, as the U.S. Department of Commerce seems to have done under the third-market test, has little economic justification. However, it is clear that, given the current law, such a strategy is sensible for the U.S. government if it wants to pursue trade liberalization with Mexico.

Simulating the Impacts of Credit Policy and Fertilizer Subsidy on Central Luzon Rice Farms, the Philippines

Mark W. Rosegrant and Robert W. Herdt

The effects of credit policy and fertilizer subsidy on farmers' input choices, production, and income are examined with a multiseason decision-making model. Stochastic production technology, risk-neutral and risk-averse decision rules, short-term savings/consumption behavior, and a dual financial market are considered. Results indicate the risk-neutral rule is more consistent with actual choices than risk-averse rules. Estimated yields increased 21% to 30% from joint credit and fertilizer subsidies. Benefits are greater on irrigated than on rainfed farms. A substantial default rate in the institutional market reduces credit program benefits.

Key words: credit policy, fertilizer subsidy, Philippines, rice, risk aversion, simulation.

Credit and fertilizer subsidies are used by policy makers in many developing countries, including the Philippines. Their effects on farmer choice of inputs, production, and income on mono-crop rice farms in Central Luzon are examined in this paper. Prior to 1973/74, few Philippine rice farmers had access to institutional credit, primarily because of high collateral requirements imposed by private banks (Sacay). A series of typhoons in 1972 reduced the rice crop by 16% over the previous three-year average, and during the same year (1972) the entire country was brought under a land reform program that was expected to restrict severely the credit traditionally provided by landlords to share-tenants. Attempting to boost rice production, the government increased the flow of low-cost credit to rice farmers in 1973/74 through a program called Masagana 99 (World Bank, chaps. 6, 7).

During Masagana 99's initial year, farmers were allowed to borrow up to 900 pesos per hectare (P/ha) per six-month season. In 1974/75 the loan limit was increased to P1,200/ha (P7.30 = US$1.00 between 1973 and 1979). These production loans are available at an effective interest rate, including service charges and discounting, of approximately 16% per year. In 1974/75, over 40% of national rice area was financed under Masagana 99, but financing declined to about 10% in 1977/78. A major cause of this decrease was the frequency of defaults on Masagana loans, disqualifying farmers from further borrowing under the program.

The primary alternative source of production loans is the informal financial market. Credit availability in this sector varies, but surveys conducted by the International Rice Research Institute (IRRI) indicate a range of effective credit ceilings of P300–P600/ha in Central Luzon. Informal market interest rates vary from 30% to 100%, with average rates of 45% to 50% (Rosegrant 1978, Manto and Torres).

The Philippine government also has subsidized fertilizer prices. A two-tier fertilizer-pricing system was established in 1973, when fertilizer supplies in the international market were growing tight and world prices were increasing rapidly. A subsidized price was established for rice and other food crops, with a higher price for export crops, set to reflect import and marketing costs. This system continued until 1975/76, after which a uniform, subsidized price applied to all crops (table 1).

Rice production increased at more than 5%

Mark W. Rosegrant is a research fellow at the International Food Policy Research Institute, Washington, D.C. Robert W. Herdt is an agricultural economist at the International Rice Research Institute, Los Baños, Philippines.

per year in the Philippines during the 1970s (U.S. Department of Agriculture [USDA]). Obviously, many factors contributed; an important question is the contribution of credit and fertilizer subsidies. Evaluation of these policy instruments can be either normative or positive. Comparison of credit program participants with nonparticipants in three Luzon provinces shows that the former borrowed roughly twice as much and spent about 50% more on rice production inputs than the latter (Herdt and Rosegrant). However, the relatively small samples studied and the effects of differences in weather, quality of irrigation, and technology prevent one from causally linking the policies with the observed differences. Also such comparisons cannot separate the effects of credit from fertilizer subsidies. Modeling the decision process within a normative framework is an alternative that meets these objectives.

The normative framework is a multiseason model incorporating stochastic production technology, risk-neutral and risk-averse decision rules, short-term savings/consumption behavior, and a dual financial market with institutional and informal sectors. Systematic behavioral assumptions govern allocation of funds within the model.

A problem with modeling credit use is that fungibility of credit permits program funds to be diverted from their intended purpose into other enterprises or consumption (Von Pischke and Adams). Diversion to alternative enterprises is a minor problem in the Central Luzon area of this analysis—IRRI farm surveys show that rice occupied 88% of the total cropped land of rice farmers in 1979, and that livestock enterprises were minimal.[1] Some diversion to consumption probably does occur despite the dispersion of credit in the form of chits redeemable in kind. However, credit regulations make this difficult to detect.

Between 1973/74 and 1975/76, rice farmers could have sold fertilizer intended for rice to the unsubsidized sugar sector, but this opportunity was limited by the small area planted to sugar in Central Luzon. Following termination of the two-tier price system, there was little opportunity for arbitrage. Adequate supplies of fertilizer were available at prevailing prices. Thus, the model estimates an upper limit of the likely production impact and provides a basis for separating the impact of fertilizer subsidies from credit subsidies.

The Model of Farmer Decision Making

Previous microlevel analyses of the impact of credit policy on farm decision making have utilized mathematical programming models (Naseem, Ladman, and Whitaker). The Ladman and Whitaker models are static, one-period models; all three models have deterministic production relationships and a single credit market. The dynamic model presented here incorporates stochastic production relationships and a dual credit market that is characteristic of rural areas in the Philippines and most developing countries.

Operation of the Model

The flow chart in figure 1 outlines the model. Initially, output and input prices and initial

[1] Rice farm labor income accounted for 90% of farm earnings and 75% of household labor earnings in another study conducted in three rice-growing municipalities of Central Luzon in 1974 (Guino). Still another study showed that in 1978 rice provided 85% of farm income in Laguna province of Luzon (Smith and Gascon).

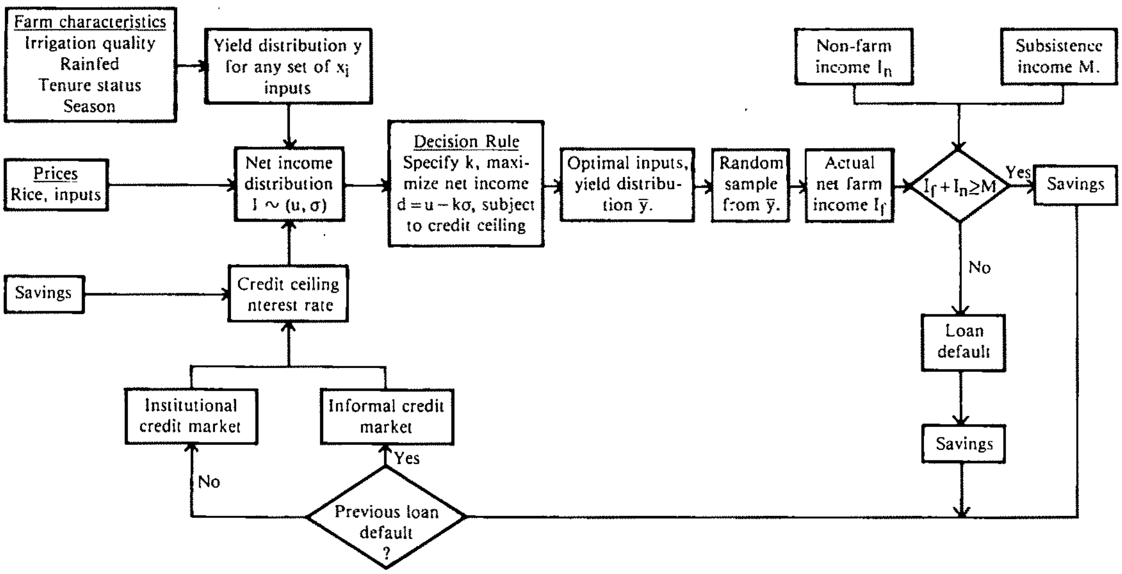

Figure 1. Flow chart of farm decision-making model

savings are set and farm characteristics specified to determine a yield distribution for any set of inputs. The financial market in which the farm borrows determines its interest rate and credit ceiling. The net income distribution for any input level can then be computed and optimal input levels chosen by the specified decision rule, subject to the credit ceiling.

The actual yield is generated by random sampling from the yield distribution corresponding to the optimal input level, and actual net income is computed. If net income plus nonfarm income is greater than subsistence requirements, savings are carried forward to the next season to begin another iteration. If total income is less than subsistence, the farm defaults on its loan and, if necessary, borrows from the informal credit market to cover subsistence requirements. Savings is computed, and the next iteration begins with the farm denied access to the institutional market because of default. If total income exceeds subsistence requirements, the farm remains in the institutional market and begins the next iteration.

To solve the model for mean input use, yield, and income over several seasons, the decision/outcome process is represented as a finite Markov chain process (Chung, Feller). The states $a_1, a_2, \ldots, a_m$ in the Markov process are determined by savings level and financial market access. Any state a_i determines input choice when the decision rule is specified and parameter values (such as rice price and input costs) are set. Input choice implies a yield distribution, which is used to compute the row of transition probabilities p_{ij}, $j = 1, \ldots, m$ of moving from state a_i at the start of one season to a_j at the start of the following season. Computation of transition probabilities for all a_i provides the Markov transition matrix. Specification of the distribution of farms across states in the initial season then permits solution of the model for the mean values of input use, yield, and income in any subsequent season.

Farm Characteristics

Farms are differentiated by tenure status (fixed or sharecrop rent), irrigation quality, seepage and percolation rates, and season of operation. The latter three define a water regime. The water regime determines the distribution of moisture stress in the production function (described below), thereby determining the frequency distribution of yield for any input level.

Prices

The prices of rice and the inputs (nitrogen, phosphorus, insecticide, and herbicide) can be set in the model to represent any desired policy mix. Actual prices of nitrogen and phosphorus are jointly determined by the prices of major fertilizer products containing these nutrients. This is reflected in the model by con-

straining the ratio of nitrogen to phosphorus at 2:1.

Decision Rules

Decision rules which have been utilized in modeling farmer behavior have been reviewed elsewhere (Anderson). A safety-first rule, to maximize the net returns which can be obtained with a fixed confidence level, is used here because it permits consistent specification of a range of attitudes toward risk (Dillon and Scandizzo, Moscardi and de Janvry, Roumasset). When the shape of the net income distribution is known, the decision rule is to maximize d, where $d = u - k\sigma$, and u is expected net income, σ is the standard deviation of net income, and k is the risk-aversion coefficient.

The coefficient k specifies the safety-first confidence level, or level of probability along the cumulative distribution of net income. For a given distribution, the larger the value of k, the greater the degree of risk aversion. If $k = 0$, the decision rule is risk neutral.

Income Allocation

Income is allocated between consumption and savings. Levels of subsistence consumption and nonfarm income are set, and income allocation behavior is specified as a marginal propensity to consume out of income in excess of subsistence consumption requirements:

$$\begin{aligned} I_t &= I_f + I_n, \\ C &= M + a(I_t - M), \\ S_t &= S_r + I_t - C, \end{aligned}$$

subject to $I_t \geq M$, where I_t is total income, I_f is farm income, I_n is nonfarm income, C is consumption, M is the subsistence consumption level, a is the marginal propensity to consume, S_t is total savings carried forward to the following production season, and S_r is savings from the previous season retained after purchase of inputs.

When total income is less than subsistence consumption, the constraint is not met, and consumption cannot be determined by the relationship above. In order to make up the consumption deficit and meet subsistence consumption requirements, the farmer fails to repay either all or part of any production loan he has obtained. Deficit-reducing behavior is determined in the financial market.

Financial Market

Farms face a capital constraint set by the level of internally generated savings and by the availability of credit from the financial market. Total spending on fixed and variable costs in a given season cannot exceed savings brought forward plus new borrowing. The maximum amount of credit available and its cost can be set within the model to reflect any desired credit policy.

Money can be borrowed from either institutional lenders or informal money lenders. All farms begin the first season with access to the institutional market for credit at a specified interest rate up to a maximum loan limit. The farm continues to borrow from the institutional market unless, because of low production caused by stochastic events, it can no longer both repay the loan and meet subsistence requirements. When this occurs, the farm defaults on its institutional loan and supplements consumption with the proceeds from the loan default up to the subsistence consumption level, allocating any additional funds between consumption and savings. If proceeds from the loan default are not sufficient to make up the difference between income and subsistence consumption, the farm borrows from the informal credit market, the farm's only other source of credit.

When the farm is in the informal market, the method for meeting subsistence requirements reflects the better enforcement of repayment and lack of alternative funding sources. In case of low production, the farmer only delays payment on the proportion of the production loan needed to achieve the minimum consumption. No additional consumption is allowed, and no savings are generated. The portion of the loan on which payment is delayed is carried over to the next season and repaid from income, along with any new production loan taken out at the beginning of the next season.

Production Function and Yield Distributions

At the core of the model are the frequency distributions of yield estimated from a highly disaggregated production function incorporating managed inputs and environmental variables. The production function is of the form:

$$y = f(x_i, v_j, q_r),$$

where $i = 1, \ldots, s; j = 1, \ldots, n; r = 1, \ldots, p$; y is yield; x_i are managed inputs (nitrogen, phosphorus, insecticide, and weed treatment); v_j are stochastic variables (solar radiation, stress days, and insect infestation index) not under farmer control and of unknown value at the time of the decision about the x_i; and q_r are variables not under farmer control but with known values (clay content). Table 2 shows the production function estimated from 674 observations taken from response experiments in farmers' fields in Central Luzon in two wet and two dry seasons. In these experiments, inputs not included in the production function were held at levels comparable to actual farm practices in the area.

The independent variables explain 72% of the variation in yields, and all variables are significant at the 0.01 level except for insecticide, which is significant at the 0.05 level.[2] Both insect infestation and insecticides are included because the usual practice is to apply insecticide after initial infestation. Labor is not included in the production function because it was held constant in the experimental plots except for that associated with applying the specified managed inputs. Labor is therefore a direct function of managed inputs.

Typhoon damage, the most important stochastic variable left out of the production function, was excluded because no typhoon damage was experienced on the experimental plots. In order to account for the impact of typhoon on yield variability, the production function was adjusted using a typhoon damage index computed from farmers' subjective estimates:

$$y' = (1 - t)\, f(x_i, v_j, q_r),$$

where t is the percentage yield loss from typhoons.

Given a production function of this form, the frequency distribution of y' for any x_i, q_r can be estimated from the joint frequency distribution of the stochastic variables t, v_j (Anderson, Dillon, Hardaker; de Janvry; Byerlee and Anderson). Lack of information about the conditional distributions of the stochastic variables precludes analytical solution of the joint frequency distribution of the variables. However, if it is assumed that the stochastic variables are independently distributed, a discrete approximation of the frequency distribution of y' for any x_i and q_r can be obtained by repetitively sampling from the frequency distributions of t and v_j and then computing point estimates of y' from the production function.[3] With sufficient iterations, 1,000 in this case, stable estimates of the moments of the distrubution of y' can be obtained and continuous frequency distributions fit using Pearson's system (Day, Elderton and Johnson).

In order to estimate the yield distributions, frequency distributions were estimated for solar radiation, insect damage, typhoon damage, and stress days, the latter under a range of water regimes representing different qualities of irrigation and drainage.

Solar radiation distributions were estimated from 1966–75 data drawn from research station records in Central Luzon. The frequency

Table 2. Yield Response Function for Modern Rice Varieties in the Philippines (kg/ha)

[c] From 60 days after transplanting to 20 days before harvest.
[d] One application of herbicide.
[e] One application of herbicide plus one handweeding.

[2] Multicollinearity is a potential problem in the production function since some variables appear in more than one term and some of the independent variables (nitrogen x solar radiation and nitrogen squared, stress days and nitrogen x stress, and stress days and solar radiation x stress) are highly correlated. However, multicollinearity is not harmful unless it causes high standard errors and lack of significance in the regression coefficients (Kmenta, Johnston). This is not the case here.

[3] The independence assumption appears reasonable. Regressions among solar radiation, stress days, and insect damage using the response function data resulted in insignificant coefficients and R^2s of 0.08 or less. The typhoon damage distribution was computed using a 1975 IRRI farm survey. Using this data, regressions among typhoon damage, drought damage (a proxy for stress), insect damage estimates, and solar radiation gave insignificant coefficients and a maximum R^2 of .11.

distribution for the insect infestation index was computed from the 674 observations over the four seasons from which the production function was estimated. The typhoon damage index was computed from farmers' estimates of typhoon damage over five crop years in Central Luzon.

A water balance model was used to generate frequency distributions of stress days for good, average, and poor irrigated sites and for rain-fed conditions, each with high, medium, and low seepage and percolation rates. The water balance model simulates weekly irrigation and rainfall. It is based on sampling from distributions of irrigation flows for sites in Central Luzon and from the distribution of rainfall recorded at Cabanatuan City, Nueva Ecija, 1949–74. Stress days are computed as a function of weekly water flows and losses from the site. Repeated iteration of the model produces a stable estimate of the distribution of stress days for any quality of irrigation and soil type (Rosegrant 1976, 1978; Wickham, Barker, Rosegrant; Wickham).

In the wet season, maximum expected yields and their standard deviations are similar for all qualities of irrigation, while rain-fed maximum expected yields are 13% lower (table 3). In the dry season, the difference between maximum yields with low and high quality irrigation is 1.3 t/ha. High quality irrigation reduces the standard deviation of yields by 30%.

The Impact of Risk Aversion

The importance of risk aversion for farmer input choices is the subject of continuing debate. Binswanger (using an experimental gambling approach with real payoffs) found attitudes highly concentrated at intermediate or moderate risk aversion. Dillon and Scandizzo (using mental experiments) report values of the risk-aversion coefficient k (from the decision rule, maximize $d = u - k\sigma$) ranging from -0.6 to 1.8, with a mean of 0.9. About 30% of their sample farmers were highly risk averse ($k > 1.5$). Neither study assessed risk attitudes in actual production decisions.

Moscardi and de Janvry estimated a corn production function, and computed the value of k which would account for the difference between actual nitrogen use and the expected income-maximizing level. The mean value of k is 1.12 with a range of 0.0 to 2.0 and a high concentration of strong risk aversion ($k > 1.2$). However, their production function did not include environmental variables such as solar radiation and moisture stress. In addition, their assumption that risk explains all the shortfall from optimal nitrogen use ignores the possible impact of constraints such as limited credit.

Roumasset explains actual nitrogen use of two samples of Philippine rice farmers using risk-neutral and risk-averse decision rules with a production function adjusted for major losses. He finds that the risk-neutral decision rule explains actual nitrogen use better than risk-averse rules.

To test the impact of risk aversion in this model, alternative decision rules were defined by specifying the risk-aversion coefficient k. Risk-neutral, moderate risk-averse, and strong risk-averse rules were tested. In the neutral case, $k = 0.0$. In the moderate case, k was set to maximize net income with probability of 0.20 on the cumulative frequency distribution of net income. The strong risk-averse rule maximizes the net income with probability 0.10 on the cumulative distribution.

Because the yield distributions, and therefore the net income distributions, have different shapes for different farm types, the value of k which specifies a given confidence level on the cumulative distribution also varies. For moderate risk aversion, k has a range of 0.62 to 0.94, with a mean value of 0.80. In the strong risk-averse case, k has a mean of 1.44 and a range of 1.34 to 1.53.

Comparison of model results with actual input use and yields suggests that the risk-neutral assumption better explains input choices than risk aversion. Model parameters,

Table 3. Yield-Maximizing Nitrogen Level, Maximum Expected Yield, and Standard Deviation of Yield, Three Qualities of Irrigation, from Estimated Yield Distributions

Season	Irrigation Quality	Yield-Maximizing Nitrogen (kg/ha)	Maximum Expected Yield (kg/ha)	Standard Deviation of Yield (kg/ha)
Dry	High	152	3,747	555
Dry	Medium	140	3,092	704
Dry	Low	124	2,455	781
Wet	High	128	2,977	833
Wet	Medium	124	2,972	828
Wet	Low	124	2,958	828
Wet	Rainfed	112	2,592	794

Note: Other inputs set at high levels: 60 kg/ha phosphorus, 2 applications of insecticide, 1 application of herbicide, and 1 hand-weeding; average soil quality.

such as prices, costs, credit ceilings, and sharing rates, were set at mean or representative values for Central Luzon, 1971/72–1977/78. The model was run for nine years (18 crop seasons), generating a distribution of farms between institutional and informal credit markets comparable to the actual distribution in Central Luzon, 1971/72–1977/78.[4]

The strong risk-averse rule generates input use and yields far below the actual levels for both irrigated and rain-fed farms (table 4). Moderate risk aversion is relatively consistent with actual results only for irrigated farm nitrogen use with the P600/ha informal loan ceiling. In all other instances, the moderate risk-averse rule produces input choices and yields considerably lower than the actual levels. Hence, the risk-neutral rule is used to examine credit and fertilizer subsidies.

The Impact of Credit and Fertilizer Policy

A subsidized credit program with increased loan ceilings, similar to those under Masagana 99, and a fertilizer subsidy comparable to that of the Philippine government were evaluated for crop years 1973/74 (the first year of Masagana 99) through 1977/78. Model parameters such as farm size, nonfarm income, wages, rents, herbicide and insecticide prices, and sharing rates were set at representative values for Central Luzon. Farm prices of rice were set at their annual prevailing level.

Fertilizer prices were set for successive runs of the model at the annual subsidized and unsubsidized rates derived from table 1. Financial market variables were set to simulate the presence or absence of a Masagana-type credit program. For model runs simulating existence of a credit program, all farms were assumed to begin in the institutional market, with a loan ceiling of P1,200/ha and an interest rate of 16% per year. The farms continue to borrow in the institutional market until default, after which they enter the informal market.

Interest rates in the informal market were set at 48% per year with maximum loan limits at P300/ha and P600/ha for alternative runs. For model runs simulating the absence of a subsidized credit program, all farms were assumed to borrow only from the informal market.

Three policies were evaluated: both the credit program and the fertilizer subsidy, the credit program with no fertilizer subsidy, and fertilizer subsidy with no credit program. In each case, the estimated impact of the policies is compared with the case of no government intervention; that is, with no credit program and no fertilizer price subsidy.

[4] Reported results are aggregated across 42 farm types: 9 irrigated types operating in wet season only plus 9 irrigated types operating in both wet and dry season plus 3 rain-fed wet season types, each then stratified by tenure status (fixed payment, share tenancy). Results are weighted by the estimated area distribution of these farm types in Central Luzon. The results are not sensitive to moderate shifts in the area distribution (Rosegrant 1978).

Table 4. Actual and Simulated Mean Input Use and Yields for Modern Varieties, Central Luzon, 1971/72 to 1977/78

		Informal Market Loan Ceiling

Combined Credit Program and Fertilizer Subsidy

The combined impact of the credit program and fertilizer subsidy is large with either informal credit market loan limit (table 5). With a P300/ha loan limit in the informal market, the combined credit program and fertilizer subsidy is estimated to increase the average nitrogen use on irrigated and rain-fed farms by 43 kg/ha, other input use by P129/ha, yields by 510 kg/ha (30%), and income by P131/ha (29%). For the P600/ha informal market loan ceiling, the estimated combined impact is reduced, but still impressive: average increases of 38 kg/ha in nitrogen use, P90/ha in other inputs, 393 kg/ha (21%) in yields, and P118/ha (25%) in income.

Irrigated farms are considerably more responsive to combined credit and fertilizer policies than rain-fed farms. They also gain higher benefits. The reasons for their higher responsiveness are to be seen in the separate effects of the credit program and fertilizer subsidy.

Credit Policy

The credit program alone produces substantial gains for irrigated farms but considerably lower benefits for rain-fed farms. For the P300/ha case, for example, irrigated farms increase yields by 22% and income by 14% due

Table 5. Estimated Increases in Input Use, Yield, and Income Due to Credit Program and Fertilizer Subsidy, 1973/74 to 1977/78

Policy	Farm Type	Nitrogen (kg/ha)	Other Inputs (P/ha)	Yield (kg/ha)	Income (P/ha)
		Informal Market Loan Limit of P300/ha[a]

	Rain-fed	6	33	207	39
	Average[b]	27	35	274	69

[a] Estimated increases are computed relative to case of no credit program and no fertilizer subsidy.
[b] Average of irrigated and rain-fed farms, weighted by area harvested in Central Luzon.

to implementation of a credit program without fertilizer subsidy, while the yield and income benefits for rain-fed farms are 7% and 9%, respectively.

Irrigated farms gain higher benefits from a credit program that releases a binding credit constraint because they can utilize higher input levels more profitably than rain-fed farms. Lower moisture stress in both seasons, and the high solar radiation and lack of typhoons in the dry season increase the marginal productivity and optimal level of nitrogen and other inputs on irrigated farms, leading to larger benefits than on rain-fed farms.

Additional runs were made to estimate the impact of reducing interest rates from 48% to 16% without increasing the availability of credit. The independent impact of such a reduction in interest rate is relatively modest: an average increase for irrigated and rain-fed farms of 5 kg/ha in nitrogen, 3% in yields, and 6% in income with the P600/ha loan limit, and 3 kg/ha nitrogen, 2% in yield, and 3% in income with the P300/ha loan limit.

The maximum interest rate impact occurs when credit is not constraining, so farmers can respond fully to price. Sensitivity tests using the model with no credit constraint show a maximum increase in yields of 5% and in incomes of 10% caused by a reduction in the interest rate from 48% to 16%. When the credit ceiling is binding, price changes are not effective. Instead, an interest rate reduction works by increasing the amount of inputs which can be financed for a given amount of credit by increasing income and savings available to finance inputs. This effect is smaller than the price impact, and causes a reduced interest rate effect when a binding loan constraint holds for some or all farms.

Default Rates

The model predicts average annual default rates on institutional market loans of 9.7% with the fertilizer subsidy and 10.6% without. As of the 1977/78 crop year in the simulated credit program, only 66% of the farmers were eligible for institutional credit in the subsidized fertilizer case and 63% in the unsubsidized fertilizer case. With a P300/ha informal market loan limit, the average yield loss due to default in 1977/78 was 8% and income was reduced by 6%. For the P600/ha informal loan limit case, the reductions in benefits due to default were approximately half as large.

Fertilizer Subsidy

The separate impact of a fertilizer subsidy in the absence of a credit program is highly dependent on the availability of credit in the informal market. With the P300/ha loan limit (which is binding on most farms), the decrease in the price of fertilizer (due to the subsidy) permits 14 kg/ha more fertilizer to be used by increasing the amount financed within the loan limit. Other input use decreases by P10/ha because a small amount of the other inputs are replaced by fertilizer which, because of the subsidy, becomes relatively more profitable. The net yield benefits of the fertilizer subsidy are 6%, with incomes increasing by 11%. Irrigated and rain-fed farms get approximately the same benefits.

With the P600/ha informal credit limit (which is nonbinding on many farms), the fertilizer subsidy boosts fertilizer use through the price impact, increasing marginal returns and optimal fertilizer levels. It also permits more fertilizer to be financed through loans. The impact of the subsidy on fertilizer use is nearly double that of the P300/ha loan limit case. With the higher loan limit, irrigated farms get 50% higher yield benefits and double the income benefits of rain-fed farms due to the higher productivity of fertilizer on irrigated farms.

Conclusions and Implications

Following the very poor harvest of 1972/73, the Philippine government instituted subsidized credit and fertilizer policies. Between 1972/73 and 1977/78, Phillipine rice production increased by 56% and rice yields increased by 38% (USDA)—an outstanding achievement, but one which could not be attributed only to government credit and fertilizer policies. Our analysis, using a dynamic model of farmer decision making, shows that credit and fertilizer policies could have induced at most a yield increase of 21%–30% for a set of farms representative of those in Central Luzon. The model correctly projected relatively large default rates from the government credit program. These occur because subsistence consumption has priority over loan repayment in years of low production caused by unfavorable weather and pest infestations. Assuming a risk-averse, safety-first decision rule resulted in poorer model validation than the alternative risk-neutral profit-maximizing behavioral rule.

The impact of a credit program that reduces interest rates and increases credit limits is larger when credit availability in the informal market is lower. The greatest impact of the credit program is in releasing the credit constraint; the independent impact of interest rate reduction is small. This confirms Adams' suggestion that higher interest rates, if they attract substantially more funds into rural financial markets, would be preferable to subsidized low interest rates and would not likely reduce production significantly.

The substantial default rate on institutional market loans causes a major reduction in long-term benefits of the credit program, reducing the number of farms with access to the institutional credit market. These defaults also reduce the effectiveness of the fertilizer subsidy since its impact increases as the availability of credit increases.

When the informal market loan limit is P300/ha, the fertilizer subsidy alone contributes less than 20% of the total yield increase attributable to the joint credit/fertilizer program. With an increase in informal market credit availability to P600/ha, the yield benefits of fertilizer subsidy alone expand to 70% of combined program benefits, even with the high interest rate in the informal market. This confirms the importance of increasing the quantity of credit to farmers so that they can utilize yield-increasing inputs.

Recreational Demands for Maintaining Instream Flows: A Contingent Valuation Approach

John T. Daubert and Robert A. Young

Recreational uses of streams, although nonconsumptive, increasingly conflict with traditional off-stream uses of water in arid regions. Recreational demands for instream flows have collective good attributes such that the recreationists' preferences may be inadequately reflected in water allocation decisions. The contingent valuation approach was adapted to impute instream flow shadow prices from a sample of recreationists on the Cache la Poudre River in northern Colorado. During periods of relatively low flows, the estimated instream flow marginal value exceeds the marginal value of water in irrigation, suggesting a need for altered water allocation policies.

Key words: contingent valuation, instream flows, public good demands, water-based recreation.

Rapidly growing demands for recreational activities using free-flowing streams have encouraged public policies to preserve or enhance instream flows. Congress approved the Wild and Scenic Rivers Act, and several western states have adopted programs to protect or increase water allocations for recreational demands. In the arid western United States, any program to maintain instream flows is potentially controversial, because it usually conflicts with existing or planned diversions for irrigation, cities, or industries. Off-stream diversion or storage of water may severely reduce flows during some periods, thereby reducing the potential quality of recreational experiences. Economics has made little contribution to the resolution of such conflicts, and most streamflow maintenance policies have been based on physical and biological criteria.

Instream flows are not subject to the same economic forces as those affecting off-stream allocations. Off-stream uses are typically for private, intermediate good production. In contrast, instream flows appear as "free goods" in relation to alternative uses. Changes in flow, affecting the stream's ability to support recreation, generate collective benefits or costs which reflect nonrivalry in consumption. Once instream flows are provided, anyone visiting the stream can enjoy the recreation experience. Even though any individual's willingness to pay for incremental changes in the flow level may be small, the aggregate benefit over large numbers of users could be large enough to warrant reallocation of water toward instream flow, away from withdrawal uses.

In resolving allocation problems, water managers are often more responsive to the tangible market-like data which reflect intermediate good demands. Relatively accurate information is available on the marginal value of water in withdrawal uses (see Young and Gray). However, measuring economic benefits from alternative flow levels is a different problem. Water managers relying only on market-related information will allocate insufficient water into recreational activities.

A workable method to measure the economic value of water left in the stream will help water managers formulate policies and

---

John T. Daubert is an assistant professor of agricultural economics, University of Arizona. Robert A. Young is a professor of economics at Colorado State University.

This research was supported by the Office of Water Research and Technology, U.S. Department of the Interior, under project COLO A-035 and by the Colorado State University Experiment Station. Several members of the staff of the U.S. Fish and Wildlife Service Instream Flow Group helped adapt their hydrologic and fishing potential models to the study sites.

The authors are grateful to their colleagues, S. L. Gray, J. R. McKean, and R. G. Walsh for advice and comments on an earlier draft. Suggestions from several anonymous reviewers are appreciated.

regulations for allocating water between instream and off-stream uses. The objective of our research was to develop and test such a method. We estimated the total and marginal willingness to pay for instream flow. The results were derived from a contingent valuation survey of three activities on a Colorado mountain stream—trout fishing, white-water boating (with kayaks, rafts, etc.), and streamside recreation (picnicking, camping, and hiking).

Earlier attempts to deal with this problem focused on measuring benefits associated with a specific recreation activity or site (Hyra). However, water managers need information about the value of water separate from the value of the related activity. Because efficient allocation among uses requires that marginal benefits of water in each use be equal, we formulated our research to estimate directly the recreationist's marginal economic value of instream flow. The measure of economic benefits is designed to be comparable with values in withdrawal uses.

Concepts and Procedures

Withdrawal and instream water uses compete for water on all of Colorado's rivers. The conflicts are typified on the Cache la Poudre River in the mountains of northwestern Colorado, a popular recreation area. During spring and early summer when the stream runoff is high, the river provides excellent white-water rapids for kayakers and rafters. The Poudre River, with its temperature, turbidity, and flow attributes, is an excellent trout fishery. More than 100,000 user days are experienced annually by recreationists visiting the canyon.

Stream flows have been diverted from the Poudre River for irrigation since 1864. Irrigation districts, by adding to or withdrawing from mountain reservoirs, can significantly raise or lower instream flows in the canyon. Up to now, such decisions have been made with little reference to recreation activities.

Concepts

Two basic approaches can determine the economic benefits of nonpriced environmental improvements (Freeman). One involves analyzing relevant market transactions in goods and services which may have substitute or complementary relationships with an environmental amenity. (The travel cost approach to measuring recreation benefits is a prime example, e.g., Knetsch.) Alternatively, the researcher may employ the "contingent valuation" approach using sample surveys that ask beneficiaries to identify their willingness to pay for specified levels of a nonmarketed good.

Each approach has both advantages and disadvantages for obtaining estimates of the demand for a public good such as instream flow. Most economists prefer to use market data, since such analyses are based on actual behavior rather than hypothetical situations. Many share Freeman's (chap. 5) reservations about the direct questioning approach, primarily because of the potential for strategic behavior by interviewees. Such behavior may bias results toward the respondents' preferred policies. However, the travel cost approach is too blunt for our purposes because instream flows vary unpredictably according to short-term climatic factors and withdrawal requirements. We therefore employed a direct questioning approach.

We adopted Bradford's theoretical base for the contingent valuation method of measuring public good demand. The object is to estimate a total willingness to pay (bid) function that reflects the recreationist's ranking between alternative income and instream flow quantities. Individual bid functions have the same economic meaning as indifference curves with a slope measuring the marginal substitution rate between income and instream flow levels. Maximum bid responses over all instream flow levels map out a total instream flow benefit function. Its first derivative is the marginal benefit function (also known as a compensated demand function).

Recreation activities may generate both collective and private benefits. For example, a fisherman who catches and keeps some fish receives private benefits which preclude others from deriving benefits from the same fish. Noncapture activities, such as viewing or catch-and-release fishing, generate collective benefits. To value instream flows which help produce recreation benefits, our model assumes that instream flow (unlike the actual catch, number of visits, congestion, fishing skill, equipment, and other inputs used to produce private benefits) enters the recreation production function as a collective input. For example, an increase in the stream flow enhances the fishing experience for all by in-

creasing the stream's carrying capacity at all sites. Similarly, all white-water recreationists can enjoy faster and higher rapids, and all shoreline users can enjoy the sights and sounds of a rapidly flowing stream. The specific model valuing instream flow for fishing activities is

$$(1)\quad WTP_j = g[S(F), C(F), V_j(F), Z(F), Y_j, E_j, T_j],$$

where WTP_j is a measure of willingness to pay to obtain an additional cubic foot per second in the flow for the jth fisherman; Y_j, a measure of income; T_j, an array of taste and socioeconomic characteristics; E_j, years of fishing experience; $S(F)$, specific recreation site; $Z(F)$, a measure of congestion on the stream; $C(F)$, a measure of the potential catch rate; $V_j(F)$, the number of days the individual visited the river to fish during the season; and F, instream flow, measured in cubic feet per second (cfs).

Because recreationists cannot make instream flow quantity adjustments themselves, WTP_j is a Hicksian compensating surplus value. This research used a "willingness to pay" measure rather than a "willingness to accept compensation," because water institutions allocate water rights to withdrawal users. Any instream flow strategy represents a potential Pareto improvement given the recreationist's initial water right status (Brookshire, Randall, Stoll). Following Hammack and Brown, we assume that the utility from other activities in which the individual might participate during a recreation day are independent of utility of the instream recreation experience.

The instream flow variable, F, represents the water planner's controllable policy instrument. Property rights in water under the western appropriation doctrine are usually specified in terms of the priority status of the right and the flow (in cubic feet per second) the owner can divert (Ditwiler). To increase or decrease stream flow for recreation, the public agency would need to acquire direct flow rights, release upstream storage, or change the priority sequence (i.e., the first right would be a flow requirement).

The willingness to pay for additional flow will vary according to the aesthetic qualities of the river, $S(F)$, the potential catch rate, $C(F)$, the number of visits, $V(F)$, and congestion, $Z(F)$. We used color photographs of eight different instream flow rates (in cfs) at four different sites to capture the aesthetic value of instream flow, $S(F)$. The photographs, taken at various times during 1977, showed the stream at approximately 50, 100, 200, 350, 400, 600, and 850, and 1150 cfs. (Due to the serious drought of that year, our highest flow photographs represented only about one-fourth of normal maximum flows.)

In addition, we provided each fishing respondent with technical information on the potential trout catch rate per hour, $C(F)$, river depth, and velocity at each flow rate and site combination. This information was based on a physical survey of each site to determine the cross-section profile of the stream bed. A hydrologic model (Bovee and Milhous) predicted the stream's depth and velocity at each cfs rate for each site, and a fish habitat model (Bovee and Cochnauer) was adapted to forecast potential catch rates at each site under each flow condition. The biological model indicated that the optimal rainbow and brown trout stream conditions (average over four sites) occurred when the instream flow approximated 500 cfs. When stream flow exceeds 500 cfs, the resulting velocity, depth, and turbidity reduce the Poudre River's fishing value.

The model uses potential catch rate instead of the actual catch rate (the latter being a function of the fishing population) and number of visitors. Because a flow change toward the optimum increases the number of fish the stream can support and encourages more fishermen, the actual catch rate for individuals may increase, decrease, or remain constant depending on how many others use the stream. However, the potential catch rate depends only on the stream's physical characteristics and flow.

Demographic characteristics are measured using the participant's sex, age, education, occupation, employer, and residence. The interview date served as a partial indicator of congestion. The assumption is that if congestion significantly affects the willingness to pay, those that participate on weekdays will bid higher than those who participate on weekends.

Questionnaire Design and Interview Procedures

Randall, Ives, and Eastman, and Brookshire, Ives, and Schultze were among the first to employ contingent valuation techniques using photographs of alternative environmental situations. Following the contingent valuation approach, the interviewer, using color photo-

graphs and physical stream characteristics, asked each respondent to reveal his/her willingness to pay for instream flow in terms of (*a*) a percentage addition to the present county sales tax on consumption expenditures and (*b*) an increase in a hypothetical entrance fee. (We interviewed the head-of-household participating in noncontact activities. In a test survey trial, individuals objected to being separated from their group.)

After showing the respondent the photograph representing the lowest instream flow quantity, and asking the respondent to estimate the average annual use, the interviewer asked how much he or she would be willing to pay for the experience represented by the next highest instream flow photograph. For example, the recreationist was asked to respond "yes" or "no" to the following question:

> If the entrance fee cost $__ per day, would you pay the fee so the members of your household could travel up the Poudre River Canyon to (*activity*) for __ day(s) of annual use, if that amount resulted in an increase in water flow from those in Picture A to Picture B?

The interviewer started the bids at $1 for the entrance fee game and at an addition of 0.1% to the sales tax rate for the sales tax game. If the respondent answered with a "yes," the interviewer raised the bid by $0.25 or 0.1% increments until the respondent answered "no." The dollar amount or tax rate at the last "yes" response was taken to be the household's maximum willingness to pay for specific instream flow improvement. The interviewer then repeated the questions assuming the respondent's average annual use was increased and then decreased by 50%. The process was then repeated for the other sites.

Because few individuals could visualize the expenditure implications of a specific percentage increase in sales tax, the interviewer first presented a table showing the annual dollar equivalent of the percent change in sales tax by family size and income. For example, a 0.1% addition to the sales tax rate for a family of four earning $20,000 represented a bid of $1.50.

The survey obtained 134 personal interviews of recreationists using the Poudre River during the summer of 1978. The sample included 49 fishermen, 45 shoreline recreationists (those camping, hiking, viewing, etc.), and 40 white-water enthusiasts (kayakers, rafters, and tubers). A benefit function was estimated for each activity. (See Daubert for further details, including the questionnaire and the photographs.)

To assure a representative and random sample of recreationists, interviews were conducted on random days during each month at various sites in the canyon. Although the survey took about an hour to complete, the acceptance rate exceeded 80%. Fishermen and shoreline recreationists were the most receptive, with only 7% and 19%, respectively, refusing the interview. However, kayakers and rafters often objected to the interruption, with 38% refusing.

A few recreationists responded with very low or zero bids. These recreationists were further questioned to establish if they were actually unwilling to pay for instream flow or if they were in fact protesting either payment method. Protest responses were not included in the final analysis. Respondents were somewhat more likely to protest the sales tax game than the entrance fee game. Possibly those with low utility for added stream flow realized that they would be helping to pay for others' enjoyment. Shoreline participants had the highest rate of protest against either game. Unlike fishing and white-water activities, higher instream flows are not crucial to enjoy shoreline recreation. This recreation group has less motivation to pay.

Results and Discussion

A priori reasoning suggests that the total bid curve will likely be nonlinear in relation to stream flow, and that it might be shifted by socioeconomic characteristics of the respondents. We used stepwise least squares regression to estimate parameters of the individual stream flow value equations for combinations of the variables shown in table 1. Household responses for shoreline activities were expressed in individual terms by dividing each response by the number of reported household members. After preliminary analysis, the final model was based on individual t-statistics, the sign on the estimated coefficients, and the stability of the coefficients on the flow quantity variable. In general, the coefficient on *Flow* and $[Flow]^2$ was insensitive to changes in model specification. Regression results are shown in table 2.

The fishing and shoreline regression equations, in the absence of congestion, showed total willingness to pay increasing at an in-

Table 1. Variables in Regression Models

Dependent Variable	
WTP:	Total willingness to pay (bid) per recreation day, activity i; respondent j; instream flow rate; for each payment alternative
Independent Variables	
Numerical variables	
Flow:	River stage in cubic feet per second (cfs)
Activity days:	Total number of annual recreation days in activity i by respondent j in Poudre Canyon
Substitute days:	Number of water-based activity days on alternative rivers
Experience:	Years of participation in activity i by respondent
Income:	Annual household income of respondent
Age:	Age of respondent
Education:	Years of schooling of respondent
Zero-one dummy variables	
Site:	Site of photograph (four sites)
Sex:	$M = 1$, $F = 0$
Occupation:	(*a*) Professional; (*b*) business owner; (*c*) skilled worker; (*d*) sales; (*e*) clerical; (*f*) unskilled; (*g*) housewife; (*h*) retired; (*k*) student
Employer:	(*a*) Manufacturer; (*b*) construction; (*c*) retail; (*d*) financial; (*e*) health; (*f*) education; (*g*) public sector; (*h*) agriculture; (*k*) unemployed

Date of interview:	(*a*) Month; (*b*) weekday; (*c*) weekend

creasing rate for flows between 0 and 200 cfs and increasing at a decreasing rate up to approximately 500 cfs (700 cfs for shoreline willingness to pay), then finally decreasing. White-water recreation models, however, did not follow that pattern. Instead, total willingness to pay increased for all instream flow quantities photographed. This may be because the 1977 drought caused maximum flows in our photographs to fall short of levels at which diminishing marginal utility would be observed.

The final quadratic regression equation for fishing and shoreline activities and the linear white-water equation fit the data reasonably well for a cross-section survey. Fishing entrance fee and sales tax equations explain 41% and 43%, respectively, of the variation in household willingness to pay. Shoreline entrance fee and sales tax equations explain 52% and 50% of the bid variation. The R^2's of white-water entrance fee and sales tax equations are .52 and .66, respectively.

Instream flow quantities are the principal determinant of fishing and white-water willingness-to-pay responses. According to t-ratio tests, *Flow* and $[Flow]^2$ are highly significant. Inspection of successive solutions of the stepwise regression indicate that *Flow* and $[Flow]^2$ explain, respectively, 20% and 21% of household fishing bid variations. Flow, alone, is highly significant in the white-water model (t-ratios equal to 15.05 and 21.68 in the entrance fee and sales tax models) explaining 38% and 53% of the bid variation. Even though *Flow* and $[Flow]^2$ are significant (t-ratios equal 2.29 and 2.18) in the shoreline user models, these variables explained only 3% and 6% of the bid variation. Since instream flows provide primarily visual aspects of noncontact recreation experiences, those users seem relatively indifferent between alternative instream flow levels except when the Poudre River is very low or extremely high. Other factors (tastes, visitation, for example) are more important in determining willingness to pay for this type of recreation.

It is possible that the variance in willingness to pay at low and high flows differs from the variance at medium instream flows. However, neither the Bartlett nor the Goldfield-Quandt tests rejected the null hypothesis that the different groupings of willingness to pay had the same bid variances (Pindyck and Rubenfeld).

Total and Marginal Value Functions

To analyze individual valuation of instream flows, we expressed the estimated equations solely as a function of flows. The equations are restated with all variables (except *Flow* and $[Flow]^2$) evaluated at their mean values. The first derivative of the total value function with respect to flow rate yields the marginal value function. The resulting equations are given below. (*TV* and *MV* are total value and marginal value, respectively.) The total value expres-

(6b) $MV = 0.019$

(7a) Sales Tax Game
$TV = -0.091 + 0.029[Flow]$

(7b) $MV = 0.029$

Possible Bias

Because bidding games may lead to strategic or biased responses, Bohm recommends that the research design include at least two different willingness-to-pay situations. One game should encourage understatement, the other overstatement. The interval between the two will be small or large depending on how strongly respondents react to the specific biases in each question design.

The estimated bid functions for the three recreation activities were statistically different for each repayment obligation; sales tax marginal benefits always exceeded entrance fee values. Sales tax responses exceeded entry fee bids by approximately $10 per day for fishing activities, approximately $5 for white-water activities. The entrance fee game, confronting each recreationist with his stated valuation, might encourage understatement. On the other hand, respondents might overstate their true preferences in a sales tax game, since payments are not a function of use and respondents know that all taxpayers would help pay for their recreation experience.

Derivation of Total and Marginal Values

We illustrate the derivation of total and marginal values by reference to the fishing entrance fee results. Table 3 presents total and marginal values derived from the entrance fee equations.

Table 3. Estimated Total and Marginal Values of Instream Flows for Fishing Activities, Poudre River, Colorado, 1978 (Entrance Fee Game)

	Total Value (WTP/day)		Marginal Value (WTP/cfs/day)

[a] Based on an average daily visit in 1978 of 228 fishermen. Source: Arapaho and Roosevelt National Forest Headquarters, Fort Collins, Colorado.

Recreation Day Values

Column 2 of table 3 shows the value per recreation day (for a representative individual fisherman) assuming no congestion effects. For fishing, the maximum value per day is about $30, at a flow of nearly 500 cfs, while lower or higher flows are significantly less valuable. (The recreational day value in shoreline activities peaks at 700 cfs, with a smaller unit day value of about $10, while the white-water value schedule increases throughout the range of the observations.)

These values would change if congestion significantly reduces the individual's bid. While this study did not directly measure congestion effects, the mean bid by participants on weekdays was not significantly different from the mean bid by participants on weekends, even though the number of users is greatly increased. Walsh et al., however, reported significant congestion effects in another context. Thus, our values could overstate the recreationist's willingness to pay.

The estimates of individual willingness to pay per day for water-based recreation are comparable with other estimates. Gordon, Chapman, and Bjornn reported travel cost results for fishing for salmonids on Idaho streams as ranging from $23 to $34 per day. Charbonneau and Hay estimated a daily value of $25 for trout and landlocked salmon from the U.S. National Sample of Anglers via a bidding game approach. (Both of these estimates are adjusted to reflect 1978 price levels.)

Aggregate Values

Column 3 of table 3 presents the aggregate value per day resulting from the summation of individual bids according to the average participation rates as related to flow. Figure 1a illustrates these results. The aggregate values would be expected to change as both instream flow and user days changed. For each flow rate, the respondent was asked how his/her bid would change if the river were visited more or less per year. The results indicated that the bids by noncontact and white-water participants diminished as visitation increased (holding flow constant). Fishermen, however, were willing to pay more at the margin for increased visitation when instream flow approximated the optimal, and less at the margin when visitation increased at low and high flows.

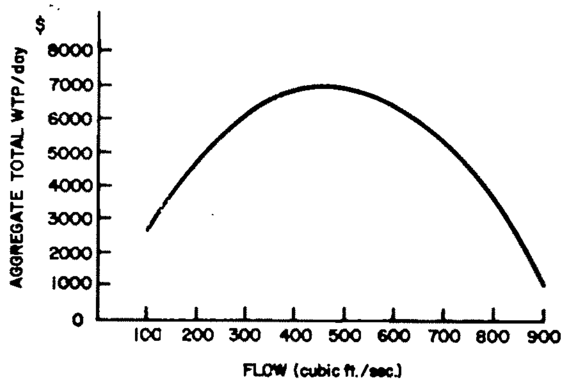

Figure 1a. Estimated aggregate total willingness to pay for flow by fishermen, Poudre River, Colorado, 1978

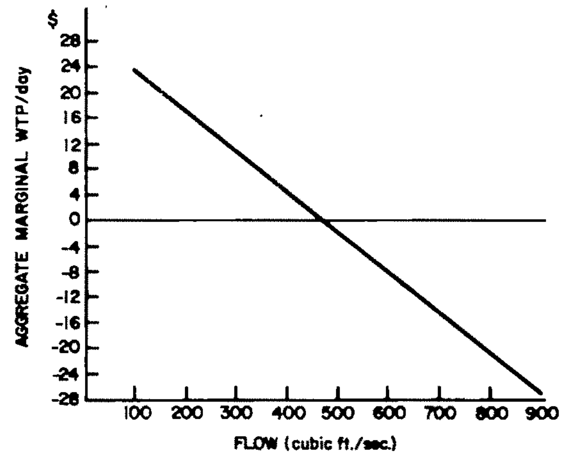

Figure 1b. Estimated aggregate marginal willingness to pay for flow by fishermen, Poudre River, Colorado, 1978

Marginal Values of Instream Flows

The primary research objective was to develop estimates of marginal value (demand) functions for instream flows. These are provided by the first derivatives of the bid functions with respect to flow. Table 3 (columns 4 and 5) contains a set of illustrative results regarding individual and aggregate marginal values for the fishing entrance fee game.

The fishing marginal value function, generally consistent with conventional economic theory, exhibits a negative slope. For example, if the Poudre River's flow is low (100 cfs), the fishing marginal instream value is relatively large, but it falls to zero as instream flows approach 500 cfs. The aggregate marginal bid (demand) function for fishing (entrance fee game) is illustrated in figure 1b. This corresponds to the total bid function in figure 1a.

Policy Comparisons

At certain locations and times, water flows in the Cache la Poudre River compete with or complement diversions and storage for crop irrigation. To compare marginal values in alternative uses, we converted the flow-based estimates into a volume measure, dollars per acre foot. Table 4 summarizes monthly estimates of marginal value of water for fishing. It also provides monthly estimates of the short-run marginal value of water for irrigation. These particular policy implications employ aggregate marginal willingness to pay only for fishing, since that activity dominates recreation values in the Poudre River area. Also, only the entrance fee results are presented.

During May, June, and July when the average monthly instream flow exceeds the optimum for fishing, recreation and crop irrigation are complementary outputs. Increased storage or diversion for irrigation upstream from fishing sites will increase both fishing and crop production. Water managers satisfying economic efficiency criteria should allocate more water to withdrawal until fishing and irrigation become competitive.

In September, present water allocation policies may not be allocating instream flows efficiently. The average September instream flow at the canyon mouth, 105 cfs, results in an aggregate marginal fishing return equal to \$10.54 per acre foot and a marginal crop return equal to \$7.22 per acre foot. To fulfill efficiency conditions, the instream flow should approximate 200 cfs where the marginal instream flow aggregate return of \$7.68 per acre foot approximates the marginal crop irrigation return of \$7.22 per acre foot. (The above assumes that this amount of water would have an insignificant impact on the marginal value of water in irrigation in the river basin as a whole.)

Our results also suggest that water managers could switch some reservoir filling from fall to spring and, thereby, increase social benefits. Many irrigation companies begin filling high mountain storage reservoirs in September and downstream reservoirs in the spring. In fact, they store over 1,000 acre feet (af) in high mountain reservoirs in September and 2,000 af in October. This water could have augmented the river's normal flow by 33 af/day and 66 af/day. Additional flow for fishing experiences is worth \$10/af in September and \$7/af in October.

Reallocating water storage from high mountain reservoirs to reservoirs near farming areas could substantially increase total benefits from water use in the fall. For example, if water managers let the 1,000 af stored in September flow downstream past major recreation areas

Table 4. Aggregate Marginal Value of Instream Flow for Fishing and Crop Irrigation by Month, Poudre River, Colorado, 1978

Flow	May	June	July	August	September	October	Average over Season

[c] Derived from Daubert, Young, and Morel-Seytoux.

before storing, total fishing benefits would increase by $380 per day or approximately $10,000 for the month. In October, when total recreation benefits would increase by at least $11,000, this water policy change increases the river's fishing benefits without decreasing next year's crop output. Water supplies remain constant or even increase; only the storage timing changes.

Conclusion

Like other environmental amenities, instream flow for recreation has collective good attributes that inhibit conventional market allocation. The contingent valuation approach was adapted to impute instream flow shadow prices by a sample of recreationists on the Cache la Poudre River in northern Colorado. By directly estimating the recreationist's willingness to pay for instream flow quantity changes, it was possible to determine marginal values of water that are comparable and commensurate with the marginal value of water in withdrawal uses. The findings indicate that variations in instream flow strongly affect fishing and white-water recreation experiences. It is less significant for shoreline activities.

The demand (marginal benefit) functions, estimated by the contingent valuation technique, seem to be plausible and generally reliable in a statistical sense. The technique successfully discriminated among the flow values in the various activities. Flow is significant to fishing and kayaking. In the range of flows considered, diminishing marginal utility was observed for fishermen but not for white-water users. While flow also was a factor in shoreline uses, it was less significant and smaller than for the other recreation activities. These kinds of estimates could provide an improved basis for water allocation decisions by management authorities. These results are relatively site-specific and it is not necessarily appropriate for decisions at alternative sites. However, we think that the method is of sufficient usefulness to recommend it for further test and refinement at other locations.

Determinants of Hunter Participation: Duck Hunting in the Mississippi Flyway

Jon R. Miller and Michael J. Hay

In this paper the authors study the relationship between habitat availability, hunter success, and the rate and intensity of participation in duck hunting in the Mississippi Flyway. Using socioeconomic data from the *1975 National Survey of Hunting, Fishing and Wildlife Associated Recreation,* and waterfowl habitat data from the 1970 Flyway Habitat Management Unit Project, they estimate probability and intensity of participation equations for duck hunting. The analysis differs from previous population-specific recreation studies in (*a*) the narrowly defined activity, (*b*) more precise definition of supply variables, (*c*) use of variables representing distance to hunting sites, and (*d*) the use of logit analysis to estimate participation probability equations.

Key words: hunting, logit analysis, recreation demand.

Increasing pressure for development of natural areas and continued growth in outdoor recreation emphasize the need for planning methodologies that improve decisions affecting recreation resources. In the case of wetlands, development is often incompatible with waterfowl hunting, an important recreational activity that requires natural habitat for a sustaining source of waterfowl and for hunting sites.

Acquisition of waterfowl habitat to prevent its alteration for agricultural purposes has been a high priority for years in the prairie pothole region of the Mississippi Flyway and is increasingly so in the Mississippi Delta bottomland area. Recently, however, there has been growing resistance to the acquisition program by those who believe agricultural development is a better use of wetlands than is their preservation as waterfowl habitat. Improved methods of estimating benefits of wetlands preservation will permit more quantitative analyses of the trade-offs involved.

Recreation, in the form of waterfowl sport hunting, is one of several important benefits provided by wetlands and the waterfowl populations they support. The focus of this paper is on the relationship between habitat availability, hunter success, and the rate and intensity of participation in duck hunting in the Mississippi Flyway. Equations such as those presented in this paper can be used to predict how the number of hunters (and how often they hunt) would be affected by continued loss of habitat and the resulting changes in hunter success. In addition, the change in days of participation may be converted to dollar magnitudes through multiplication by day values obtained from other sources.

Our analysis differs in some important ways from previous studies of determinants of recreation behavior (Kalter and Gosse; Cicchetti, Seneca, Davidson; Cicchetti 1972, 1973; Deyak and Smith). First, we examine the determinants of participation in a narrowly defined, wildlife-related, recreation activity, rather than a broad category such as general hunting or fishing. This permits more precise definitions of supply or availability variables (e.g., the use of waterfowl habitat and hunter success measures) and makes the analysis more useful for wildlife resource management. Second, we incorporate a measure of average distance traveled to hunt waterfowl as a proxy for access-related costs of hunting. Finally, in contrast to other population-specific recreation economics studies, we estimate probability of participation equations with logit analysis rather than the commonly used linear probability model.

Jon R. Miller is an assistant professor in the Department of Economics, University of Utah. Michael J. Hay is an economist with the U.S. Fish and Wildlife Service.

The opinions and conclusions presented here are the authors' and not necessarily those of the U.S. Fish and Wildlife Service.

In the next section, we discuss the estimating equations. The third section is a discussion of data sources and variables. In the fourth section we discuss empirical results with emphasis on the supply variables measuring the availability of waterfowl habitat and average hunter success. We then illustrate how the methodology of this paper could be used in policy analysis. In a concluding section we summarize and make suggestions for improving recreation participation studies.

The Estimating Equations

Any broadly based sample of individuals will include a large number who do not participate in duck hunting. Attempting to identify determinants of participation from such a sample by regressing days of participation on explanatory variables will result in a large concentration of values of the dependent variable at zero. This concentration of the dependent variable at a lower bound will result in underestimates of participation for those who participate. In such a case, the classical regression model is inappropriate (Goldberger, p. 252). To alleviate this problem we use a two-step estimating process: (*a*) estimation of probability of participation equations, and (*b*) estimation of the level or intensity of participation equations for those who participate. Estimation of the first step equation uses a logit estimation technique. Most previous recreation participation studies have used ordinary least squares (OLS) for estimation of linear probability equations in step one. Three major problems are associated with this approach: (*a*) the error terms are not normally distributed and violate the classical least squares assumption of homoskedasticity, resulting in inefficient estimators; (*b*) because the error terms are not normally distributed, *t*-tests of significance do not apply; and (*c*) predicted probabilities from the estimated equation could yield values outside the 0–1 probability interval (Goldberger, Nerlove and Press, Netter and Maynes, Zellner and Lee).

Alternative binary choice models avoid these problems. The two most popular alternatives are the probit and logit formulations.[1]

[1] Most applications of logit and probit are based on the works of Berkson and Finney. More recent applications are Heckman, Amemiya, and in this *Journal*, Hill and Kau. Particularly readable presentations of the technique may be found in Wonnacott and Wonnacott (pp. 131–4) and Pindyck and Rubinfeld (pp. 245–56).

The primary concept underlying these binary choice models is the threshold of response. In the context of this study, an individual either hunts waterfowl or does not. We assume an individual's participation decision is a function of socioeconomic characteristics and the availability of waterfowl habitat and populations. If the value of this function exceeds some threshold value for the individual, the individual will participate. For the *i*th individual, Y_i, is defined as follows:

$$(1) \qquad Y_i = \begin{cases} 1 \text{ if } I_i \geq I_i^* \\ 0 \text{ if } I_i < I_i^* \end{cases}$$

I_i^* is the individual's response threshold, and I_i is a linear function of the explanatory regressors, i.e., $I_i = \alpha + X_i'\beta$. The probit model assumes that I_i^* is a normally distributed random variable. With I_i^* distributed normally, the probability that $I_i > I_i^*$ is simply the value of the cumulative normal probability function evaluated at I_i. The cumulative normal function has an *S* shape with the probability values bounded by zero and one. Estimation is usually done with iterative maximum likelihood techniques.

Since the cumulative logistic probability function is basically similar in form to the cumulative normal function, it is often substituted for it because of its relative computational ease. In logit analysis, the probability that the individual will participate is

$$(2) \quad P_i = F(I_i) = \frac{1}{1 + e^{-I_i}} = \frac{1}{1 + e^{-(\alpha + X'_i\beta)}}.$$

The specification is more apparent if (2) is rearranged, i.e.,

$$(3) \qquad \log\left(\frac{P_i}{1 - P_i}\right) = \alpha + X'_i\beta.$$

Rather than the probability of the occurrence being a linear function of the explanatory variables, as in the standard linear probability model, the logit formulation assumes the log of the odds, or logit, is a linear function of the explanatory variables. The maximum likelihood coefficients are asymptotically consistent, efficient, and normally distributed, and the t-test is a valid test of significance. These desirable properties and the fact that the estimated probabilities are bounded by zero and one are the important advantages of logit estimation. While logit estimates are superior on theoretical and statistical grounds, compari-

sons of binary choice models show that when estimated probabilities lie within the extremes of the S-shaped curve, OLS or appropriately specified GLS estimates are similar to those of logit. Indeed, OLS-logit comparisons made in this study indicated little difference.

Our intensity-of-participation equation is based on the household production approach developed by Becker and recently adapted by Deyak and Smith for analysis of participation in outdoor recreation. While we believe the household production approach is theoretically appealing, reduced-form equations like the ones in this paper can also be derived from a more traditional supply-demand framework (e.g., see Cicchetti, Seneca, Davidson). In the household production framework, duck hunters are assumed to maximize utility functions expressed in terms of final service flows, one of which is measured as days of waterfowl hunting. The individual is both consumer and producer, combining purchased market goods, certain nonmarket goods, and time in the production of the final service flows. In the case of duck hunting, purchased goods include costs of travel, ammunition, and other equipment. Nonmarket goods include public duck-hunting sites and duck populations that are managed as common property resources by federal and state resource management agencies. As noted in the introduction, the influence of these latter variables is the prime concern in this paper. Waterfowl habitats and populations are viewed primarily as supply shifters, i.e., as the amount of habitat or the size of waterfowl populations increase, the cost to the hunter of a constant quality hunting day will fall and he will be induced to hunt more, other things remaining equal. Alternatively, availability could be viewed as a demand shifter, as the quality of hunting days would be expected to increase with availability. However, both influences are in the same direction, so we would expect the effect of availability of habitat and ducks on participation to be unambiguously positive.

The result, described in detail in Miller and Hay, and Deyak and Smith, is a reduced-form equation in which the number of days of duck hunting is a function of exogenous shifters of the individual's demand and supply (marginal cost) curves. Because it is a reduced form, the coefficients of this equation cannot be interpreted as either demand or supply structural parameters, but rather as measures of the joint effects of both supply and demand. The equations cannot be used to estimate economic values of hunting days or bagged ducks. Moreover, the lack of information in our survey data on the location of an individual's hunting activity, other than by state, precludes techniques such as the disaggregated travel cost approach (Brown and Nawas; Gum and Martin) to obtain value estimates. The methodology presented in this paper, however, is related to economic valuation. Recreation benefit evaluations typically provide estimates of participation and average or marginal values of a day of the activity under study. However, these evaluations are not designed to account for changes in participant numbers or level of activity over time as a result of changes in policy-related variables such as habitat and game populations. Participation studies, like the one presented here, help to fill this gap and permit broader use of such economic value estimates.

Data Sources and Definition of Variables

The primary source of data used in our empirical estimates is the *1975 National Survey of Hunting, Fishing and Wildlife Associated Recreation* (U.S. Fish and Wildlife Service). The survey was conducted in two stages. The first stage consisted of a national telephone survey of a stratified sample of some 106,000 households nationwide. The telephone interview with the household head or other adult household member gathered demographic information about each member of the household and whether he or she had hunted or fished in the preceding year. The survey also asked if household members had engaged in wildlife watching or photography during the past year, and, if so, how often. Certain other data were also gathered. The second stage of the survey consisted of mailing questionnaires, with two follow-up mailings if needed, to a nationwide sample of hunters and fishermen identified in the telephone survey. In all, the survey resulted in usable information for more than 330,000 individuals in the telephone survey and more than 20,000 individual hunters and fishermen in the mail survey.

Estimating probability of participation in an activity based on survey data requires that the sample of individuals include some who participated in the activity of interest and some who did not. In our case, the telephone survey includes those who hunted in 1975 and those

who did not, but does not indicate what kind of hunting was engaged in (waterfowl, big game, etc.). More detailed information was gathered in the mail, follow-up survey. Hence, we divide our first-step probability estimation into two substeps; first, the probability that an individual engaged in hunting of any kind in 1975, and then, given that he hunted, the probability that he hunted ducks. Due to the large sample size generated in the telephone survey, the equation in the first substep is estimated with a randomly drawn subsample of hunters and nonhunters from the telephone phase of the survey. A probability-of-participation-in-duck-hunting equation is then estimated using all of the sample hunters in the Mississippi Flyway, some of whom hunted ducks while others did not. The second-step or level of participation equation is estimated for only those Mississippi Flyway hunters who had hunted ducks.

Table 1 shows the explanatory variables used in our equations. Most of the variables are standard measures and require no further explanation. The supply-related variables are based on state level data from sources other than the 1975 Survey. They are assigned to each individual in the sample based on his state of residence. For example, the variable *ACRES* is a per capita measure of public recreation areas and commercial forests and is included in the probability-of-hunting equations to represent relative availability of open space for hunting. Data on public recreation land area are derived from the results of the U.S. Bureau of Outdoor Recreation's unpublished *1972 Public Outdoor Recreation Areas and Facilities Inventory*. Commercial forest

Table 1. Definition of Variables

Variable Name	Definition	Units of Measurement
AGE	Age of respondent	years
AGESQ	Square of respondent's age	years
INC	Respondent's household's income	thousands of dollars
SEX	Sex of respondent	1 – if male 0 – otherwise
PREF	Intensity of preference for waterfowl hunting	1 – if waterfowl hunting is favorite activity 0 – otherwise
METRO	Metropolitan residence	1 – if residence is in metropolitan area 0 – otherwise
NONCON	Nonconsumptive fish and wildlife participation	1 – if respondent reported having observed or photographed wildlife in 1975 0 – otherwise
BAG	1974 average season bag of ducks per hunter in the respondent's state of residence	number bagged
MILES/DAY	Total season round trip automobile miles driven by the respondent for migratory bird hunting divided by total days of participation in the activity	miles per day
ACRE	Acres of public recreation land plus acres of commercial forest in respondent's state of residence	acres per capita
WHAB	Acres of waterfowl habitat in respondent's state of residence	millions of acres
WETHAB	Acres of wetlands and permanent water habitat in respondent's state of residence	millions of acres
UPHAB	Acres of upland waterfowl habitat in respondent's state of residence	millions of acres

acreage is from U.S. Department of Agriculture (USDA, p. 20). Per capita measures of this variable are used to capture the effect of general population and congestion pressures on the availability of hunting opportunities. General population, rather than hunter population, is used as the per unit measure, since other activities may affect the availability or suitability of hunting sites.

The measures of waterfowl habitat (*WHAB*, *WETHAB*, and *UPHAB*) are based on the Flyway Habitat Management Unit Project (U.S. Bureau of Sport Fisheries and Wildlife). That project produced estimates for 1965 of the acreage of three types of waterfowl habitat in each of the coterminous forty-eight states. The three habitat types are wetlands, permanent water, and upland habitat. More recent estimates are not available. The bag (hunter success) variable is derived from data compiled yearly by the U.S. Fish and Wildlife Service and reported by state and flyway (Carney, Sorenson, Schroeder).

Empirical Results

Three equations representative of the type of hunter participation analysis possible with the 1975 Survey data are presented here. More detailed empirical work may be found in Miller and Hay. Equation (4) is the estimated relationship between the log of the odds (logit) of hunting in general and hypothesized determinants of hunting. Equation (5) is a similar relationship for duck hunting. The coefficients represent the derivatives of the log of the odds with respect to the explanatory variables. The corresponding relationships to the probability of participation, P, are nonlinear. The partial derivatives of the nonlinear probability function evaluated at sample means appear below the asymptotic t-statistic shown in parentheses beneath the coefficients. The likelihood ratio index (*LRI*) is a logit analogue to the multiple correlation coefficient in least squares regression (Domencich and McFadden, p. 124), and is defined as

$$LRI = 1 - (\text{log likelihood at convergence/log likelihood at zero}).$$

$\bar{P}$ is the proportion of the sample that participated.

$$(4)\quad \ln\left(\frac{P}{1-P}\right) = \underset{\substack{(8.92)\\0.001}}{-5.764 + 0.156\,AGE} \;\; \underset{\substack{(-9.02)\\ —}}{-\,0.002\,AGESQ} \;\; \underset{\substack{(11.69)\\0.140}}{+\,2.463\,SEX} \;\; \underset{\substack{(1.33)\\0.015}}{+\,0.264\,HEAD} \;\; \underset{\substack{(-7.75)\\-0.015}}{-\,0.933\,METRO} \;\; \underset{\substack{(5.17)\\0.038}}{+\,0.666\,NONCON} \;\; \underset{\substack{(3.92)\\0.001}}{+\,0.021\,ACRES},$$

where $LRI = .263$, $\bar{P} = .137$, and $n = 2{,}752$. All coefficients in equation (4) are significant at the 1% level except the head of household dummy, significant at the 9% level. The quadratic relationship between *AGE* and the log of the odds indicates that increasing age affects hunting participation positively up to a point and then has an overall negative effect, other things being equal. Based on the coefficients of equation (4) the maximum probability of hunting occurs at age thirty-nine. This inverted U-shape relationship is in contrast to the findings of Cicchetti (1973), who reported that the probability of hunting was higher for young and for retired persons than for those in the middle age groups. Two other socioeconomic or demand-related variables have significant coefficients. Not surprisingly, men are more likely to be hunters than women. The negative *METRO* coefficient indicates that persons living in urban areas are less likely to hunt than individuals in nonmetropolitan areas, other things being equal. The coefficient of *ACRES* is significant with the expected positive sign. The positive coefficient of *NONCON*, the wildlife observation/photography dummy, suggests that consumptive (hunters) and nonconsumptive wildlife users (observers and photographers) may not comprise separate groups as is often suggested. Significant overlap exists. Hunters frequently take nonhunting, scouting trips to check potential hunting sites and game populations. In addition, a significant portion of the benefits of hunting is nonconsumptive in nature. Many people hunt primarily to experience nature, and to escape the stresses of the man-made environment. Hunters with such preferences likely take nonhunting trips for those types of benefits.

Equation (5) presents estimates of the determinants of participation in duck hunting, conditional on being a hunter.

$$
\begin{aligned}
(5)\ \ln\left(\frac{P}{1-P}\right) = {} & \underset{(8.06)}{2.673} - \underset{\substack{(-7.52)\\-0.005}}{0.026}\,AGE \\
& + \underset{\substack{(3.57)\\0.187}}{1.004}\,SEX + \underset{\substack{(4.71)\\0.004}}{0.019}\,INC \\
& - \underset{\substack{(-1.81)\\-0.034}}{0.180}\,METRO + \underset{\substack{(6.59)\\0.027}}{0.145}\,BAG \\
& + \underset{\substack{(6.28)\\0.058}}{0.313}\,WETHAB + \underset{\substack{(3.26)\\0.028}}{0.153}\,UPHAB,
\end{aligned}
$$

where $LRI = 0.064$, $\bar{P} = .27$, and $n = 2{,}786$.

These estimates focus the analysis more narrowly. The analysis is restricted to duck hunting in the Mississippi Flyway, and some notable changes occur in comparison to the more general equation (4). Again, all coefficients are significant at standard levels. The effect of *AGE* on the probability of participation is distinctly different for duck hunting than for hunting in general. Here the effect is negative throughout, with no U-shape relationship as was the case previously. The coefficient of income is positive and significant in these estimates, whereas it was not a significant determinant of the probability of participation in general hunting. This means that, among hunters, as income increases, the probability that an individual hunts ducks also increases, holding age and other factors constant. The coefficient of *SEX* is again positive, indicating that if women hunt, they are less likely than men to hunt ducks. The variables included as measures of duck hunting opportunities have the expected positive coefficients and consistently high t-ratios.

Average season bag per hunter in the respondent's state of residence (*BAG*) is a measure of hunter success in 1974. Success in the preceding year was thought to be the relevant measure for the decision whether to hunt or not in 1975. Average bag in the year of the activity could be used as an alternative success variable, as hunters may be induced to hunt if they perceive the current hunt to be going well. Including both variables in the same equation, however, resulted in a high degree of multicollinearity.

The measure of habitat availability is disaggregated into acres of wetlands including permanent water (*WETHAB*) and upland habitat (*UPHAB*). The coefficients of both variables are significant, with the partial derivative of *WETHAB* twice as large as that of *UPHAB*. This means that changes in availability of wetlands as hunting sites have more impact on duck-hunting participation rates than do changes in upland habitat, other things being equal.

The interpretation of these statistical estimates of the effects of success and habitat when entered as separate explanatory variables is also of policy interest. The positive coefficient of *WETHAB*, holding the bag measure constant, means that the rate of participation in duck hunting is expected to decline if wetland acreage decreases, even if hunter success is maintained at current levels by more intensive management of remaining habitats. The reduction in participation may result from increased access cost as wetlands decline, and from the negative impact of increased congestion on remaining sites.

Equation (6) is a logarithmic specification of a level-of-participation equation. The sample consists only of respondents who hunted ducks.

$$
\begin{aligned}
(6)\ \ln(DAYS) = {} & \underset{(0.39)}{0.202} + \underset{(2.70)}{0.110}\ln(INC) \\
& + \underset{(9.33)}{0.793}\,PREF + \underset{(3.00)}{0.252}\ln(BAG) + \\
& \underset{(1.87)}{0.079}\ln(WHAB) - \underset{(2.70)}{0.110}\ln(MILES/DAY),
\end{aligned}
$$

where $R^2 = .21$, $F = 34.64$, and $n = 627$. Some variables appear in this equation but not in equations (4) and (5). Preference intensity, *PREF*, has a strong positive impact on days of participation. Hunters who indicated that waterfowl hunting was their favorite hunting and fishing activity hunted ducks more than twice as many days in 1975 as did those who preferred another activity, other things being equal.[2]

The addition of a distance-travelled-to-hunt variable improves the overall fit of the step two equation. Miles per day is included as a proxy measure for the cost of access to hunt-

[2] In the multiplicative functional form, an intercept dummy variable such as *PREF* has the effect of increasing the intercept term, e^{β_0}. Thus, when $PREF = 1$, the intercept is $e^{\beta_0+\beta_1}$ where β_1, is the coefficient of *PREF*, and Y is e^{β_1} times larger than when $PREF = 0$.

ing sites. The most notable effect of the distance-travelled variable is that when *MILES/DAY* is included in the equation, *METRO* is no longer statistically significant. This suggests that the significance of *METRO* in the probability equations reflects the influence of access costs rather than urban-rural taste differences. Note that income has a positive effect on level of duck hunting, as it does in the probability equation. *WHAB*, measuring habitat availability, combines *UPHAB* and *WETHAB* which were not significant in equation (6) when entered separately.

Participation equations typically are used to test hypotheses about determinants of participation and to forecast numbers of participants and days of an activity. Hypothesis testing in terms of the effect of age, income, and other factors was discussed above. Forecasting, and the use of the estimates for policy purposes, can be illustrated by considering the effects on duck hunting of a 10% loss of waterfowl habitat in each state in the Mississippi Flyway, an average of 204,900 acres per state.

The reduction in habitat has the effect of reducing the number of duck hunters, as well as the number of days hunted by those who continue. Based on approximately 6.5 million hunters of all kinds in the flyway in 1975 and using partial derivatives from equation (5), a 10% habitat loss would reduce the probability that a hunter hunts ducks by .0087, resulting in 56,550 fewer duck hunters. If we assume those hunters would have hunted the sample average of 8.5 days per hunter, this implies a reduction of 480,675 hunter days. The days lost because those who still hunt ducks would hunt less often, estimated at .07 fewer days per hunter from equation (6), gives a further reduction of 118,892 days. Using $29 as the estimated consumer surplus value of a day of waterfowl hunting (Charbonneau and Hay), the total reduction of 599,567 days amounts to an annual loss of $17 million. Discounted at 7-3/8%, the annual loss has a present value of $235 million, representing an average value for duck hunting of $82 per acre of habitat. If, as one would expect, the loss of habitat leads to a lower average bag per hunter, there would be further reductions that could be taken into account by means of the bag variables in the probability and level of participation equations if the relationship between acres of habitat and hunter bag could be quantified.

Summary and Conclusions

Our main purpose was to improve the analysis of the relationship between habitat availability, hunter success, and the rate and intensity of participation in duck hunting. We presented examples of probability and intensity of participation equations estimated with data from the *1975 National Survey of Hunting, Fishing, and Wildlife Associated Recreation.*

Several variables of policy interest were statistically significant in determining hunter participation, e.g., waterfowl habitat and average bag levels. Equations estimated in this paper can be used to assess the effects on hunter participation of policy-related changes in waterfowl habitat and hunter success. Probability-of-participation equations were used to predict the change in the number of hunters, and days of participation equations to predict the change in the level of hunter activity. The estimates indicate that the reduction in duck hunting that would result from a 10% loss of waterfowl habitat in the Mississippi flyway has a discounted present value of $108 million. Estimation of the indirect relationship between habitat, game populations, and hunter success would require additional information.

Data limitations require that our empirical results be used cautiously. Our inability to determine from the survey data the extent of multiday trips is important, as is the lack of precise information on the location of the activity. Studies of waterfowl hunting and other fish and wildlife-associated recreation would benefit from improved and more extensive data on wildlife populations and their habitats. These data should be organized in geographical units (e.g., states, counties, game management units) which lend themselves to policy studies.

Our analysis has shown that differences in habitat availability and hunter success influence both the probability and intensity of waterfowl hunting. Our methods for assessing these impacts have considerable promise. Improved data and additional studies like this one can build confidence in the estimation techniques and, therefore, encourage a broader use of empirical results in planning and analysis.

Evaluating Returns to Agricultural Research: A Review

George W. Norton and Jeffrey S. Davis

This paper reviews and compares the most common approaches used to evaluate public agricultural research investment. *Ex post* studies fall into two major groups: (*a*) consumer and producer surplus analyses, estimating average rates of return to research, and (*b*) production function analyses, estimating marginal rates of return to research. *Ex ante* studies fall into four groups: (*a*) those using scoring models to rank research activities, (*b*) those employing benefit-cost analysis to establish rates of return to research, (*c*) those using simulation models, and (*d*) those using mathematical programming to select an optimal mix of research activities.

Key words: literature review, public investment, research evaluation.

As public investment in agricultural research has expanded, attention has focused on its productivity and the efficiency with which funds are allocated. Decision makers desire information on research payoffs in order to assess alternative uses for public funds. In addition, the public itself is increasingly concerned about the productivity of its tax dollars.

This paper reviews the major research techniques that have been developed to evaluate returns to agricultural research. It extends previous reviews of Peterson (1971), Shumway (1973, 1977), Easter and Norton, Peterson and Hayami, Sim and Gardner, Schuh and Tollini, and Scobie (1979). We follow the Schuh and Tollini procedure of categorizing returns to research studies into *ex ante* and *ex post* evaluations. Major studies which illustrate each technique are discussed and compared to show (*a*) differences in assumptions made in studies using similar methods, (*b*) techniques appropriate to answer different questions, and (*c*) incomplete areas where methodology needs development or improvement.

George W. Norton is an assistant professor in the Department of Agricultural Economics, Virginia Polytechnic Institute and State University. Jeffrey S. Davis is an economist with the New South Wales Department of Agriculture, Australia.

This research was supported in part by funds from the North Central Region Agricultural Experiment Stations and by Cooperative Research, SEA USDA.

The authors thank Burt Sundquist, Willis Peterson, Vernon Ruttan, Yoav Kislev, and Robert Lindner for their helpful comments without implicating them in any remaining errors or omissions.

Ex Post Evaluations

Ex post evaluations fall into two major groups: (*a*) those using consumer and producer surplus directly and estimating an average rate of return to research, and (*b*) those estimating a marginal rate of return to research by treating research as a production function variable. In addition, there are two major studies outside these two classes: one estimates the impact of technology on national income and the other measures the nutritional impact of agricultural research.

Consumer and Producer Surplus Approach (The Index Number Approach)

Schultz (pp. 117–22) attempted the first major quantitative evaluation of agricultural research investments by calculating the value of inputs saved through more efficient production techniques compared to the cost of research and development. He estimated that output per unit of input was at least 32% higher in 1950 than in 1910. To have produced 1950 output with 1910 techniques would have required \$39.6 billion worth of inputs rather than the \$30 billion actually used (using 1910–14 price weights). He also derived an upper limit using 1946–48 price weights. In effect, he calculated the increase in consumer surplus resulting from the savings in inputs under the special conditions reflected in figure 1. The area under the completely elastic sup-

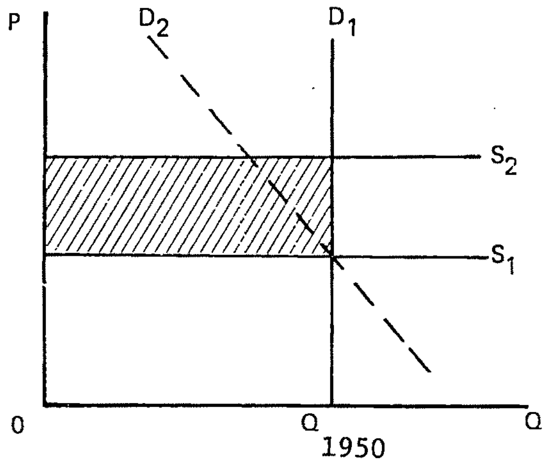

Figure 1. Value of inputs saved

ply curve S_1 to the left of the complete inelastic curve D_1 represents the total cost of producing 1950 output with 1950 techniques. The area between S_1 and S_2 to the left of D_1, represents additional resources required to produce that output with 1910 techniques.

Schultz pointed out that a downward bias in research returns resulted from this estimation because all public research and extension expenditures were not aimed at producing and distributing new techniques. An upward bias resulted from neglect of private research and from the implied perfectly inelastic demand curve. This bias is likely to be small for agricultural products because of their low demand elasticity.

Since Schultz's work there have been many consumer-producer surplus (CS) research evaluation studies, most at the commodity level. General discussions of consumer surplus concepts can be found in Currie, Murphy, and Schmitz; Hertford and Schmitz; and Willig. Griliches (1958) calculated the loss in net social surplus if hybrid corn were to disappear. His analysis assumed that adoption of hybrid corn shifted the supply curve for corn downward or to the right. He estimated returns for the polar cases of perfectly elastic (fig. 2) and perfectly inelastic (fig. 3) supply curves, implicitly assuming a unitary demand elasticity.

In figure 2 the change in consumer surplus equals $E + F$, which equals $KP_1Q_1(1 - \frac{1}{2}Kn)$ where $K = \frac{\Delta P}{P_1}$ and n is the absolute value of the demand elasticity. In figure 3, the change in net economic surplus equals $A + B - A + C$

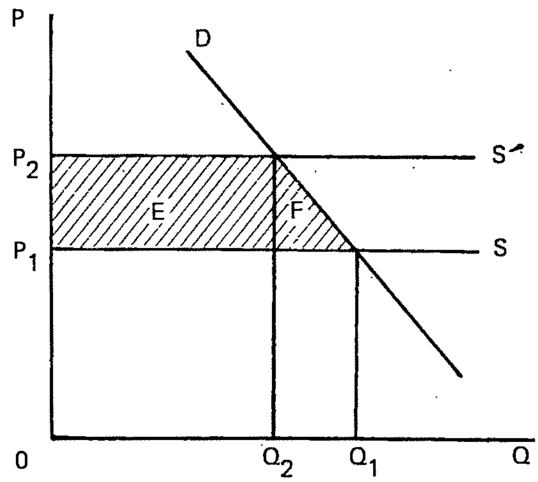

Figure 2. Hybrid corn, perfectly elastic supply

which equals $KP_1Q_1\left(1 + \frac{1}{2}\frac{k}{n}\right)$ where $K = \frac{\Delta Q}{Q_1}$.

Peterson (1967) developed a formula for estimating net social surplus changes for poultry research which eliminated Griliches's supply and demand elasticity restrictions. As illustrated in figure 4, when price and quantity move from P_1 to P_2 and from Q_1 to Q_2, respectively, Peterson's change in net economic surplus $= A + B + C + E + G + (-A - B + H + I + J) = C + E + G + H + I + J$. He reasoned that this area is approximately equal to $I + J + K + L + E + G - D$ and provided the following expression to approximate it:

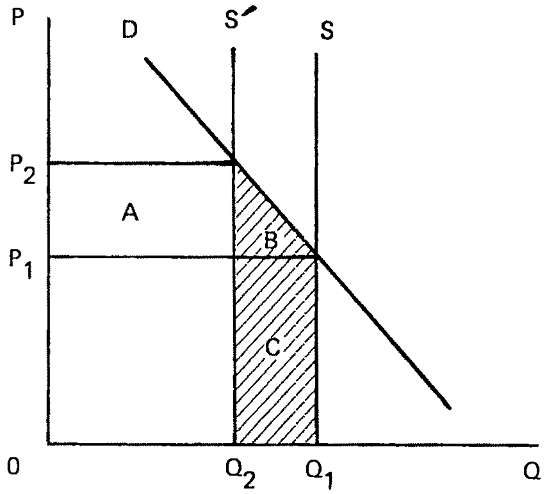

Figure 3. Hybrid corn, perfectly inelastic supply

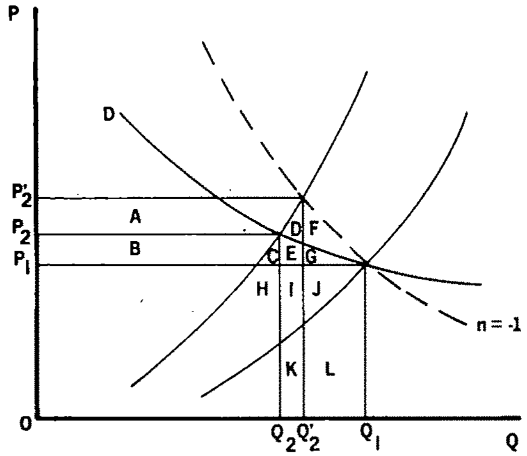

Figure 4. Poultry supply shift resulting from the use of new inputs

$$(1) \quad KQ_1P_1 + \tfrac{1}{2}K^2P_1Q_1/n - \tfrac{1}{2}Q_2K^2P_1\left(\frac{P_1}{P_2}\right)\left(\frac{en}{n+e}\right)\left(\frac{n-1}{n}\right)^2,$$

where n is the absolute value of the demand elasticity, e the supply elasticity, and K the percentage shift in the supply curve $\frac{Q_1 - Q'_2}{Q_1}$. He compared this with costs of research and extension and calculated an internal rate of return. The above expression reduces to

(2) $KQ_1P_1(1 + K/2n)$ if $n = 1$ or $e = 0$.

Hertford and Schmitz provided the following formulas for estimating changes in net social surplus if the demand and supply curves represented in figure 4 are linear and the supply shift is parallel:

(3) change in total net social surplus

$$= KP_1Q_1\left(1 + \tfrac{1}{2}\frac{K}{n+e}\right),$$

(4) change in consumer surplus

$$= \frac{KP_1Q_1}{n+e}\left(1 - \tfrac{1}{2}\frac{Kn}{n+e}\right),$$

(5) change in producer surplus

$$= KP_1Q_1\left\{1 - \frac{1}{n+e}\left[1 - \tfrac{1}{2}K\left(\frac{2n+e}{n+e}\right)\right]\right\},$$

where K is defined as the horizontal distance between S' and S.

Schmitz and Seckler extended the model to account for resources (labor) released with the introduction of new technology (the mechanical tomato harvester). They estimated net benefits as "value of inputs saved" minus "value of labor lost." First they assumed displaced labor would receive no compensation; then they assumed alternative compensation levels.

Ayer and Schuh (1972) altered the model to make Brazilian cotton supply dependent on the previous year's price. In figure 5 S and S' is the supply of cotton fiber when improved and unimproved varieties respectively are planted; D is the demand for cotton fiber; and S' is shifted $K\%$ to the left of S as a result of lower fiber yield in old varieties. They estimated demand and supply equations and collapsed them into two dimensions. Hence D was represented by $P = nQ^{\alpha}$, S was represented by $Q = mP_{t-1}{}^{\beta}$, and S' was represented by $Q = (1 - K)mP_{t-1}{}^{\beta}$. In this case n and m are parameters representing all demand and supply shifters, respectively. The change in net social benefits for each year was

$$(6) \quad \int_0^A (D)d(Q) - \int_0^A (S)d(Q) - \int_0^E (D)d(Q) + \int_0^E (S')d(Q).$$

The authors varied elasticities and K-values to test the sensitivity of their results and examine the distribution of consumer and producer benefits. The change in consumer surplus $= P_2BC - P_3FC = P_2BFP_3$. The change in producer surplus $= 0ABP - 0AH$.

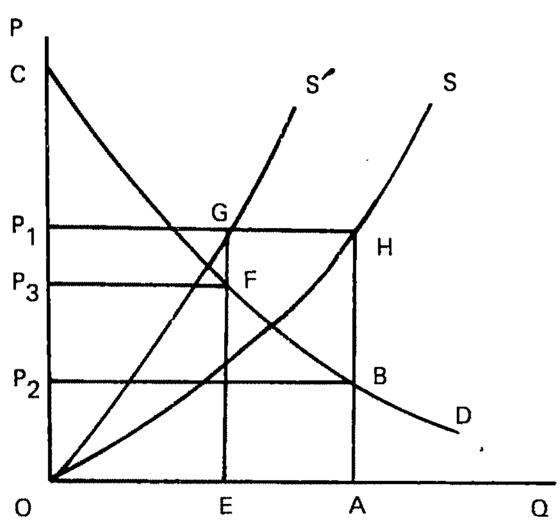

Figure 5. Cotton supply shift resulting from the use of new varieties

Akino and Hayami used a similar approach to estimate social benefits in Japan from rice-breeding research, including distributional effects of rice import policies. In figure 6 actual demand and supply curves are represented by D and S, while S' represents the supply curve that would have existed in the absence of improved varieties. Assuming market equilibrium and no rice imports, the change in net surplus due to research equals $AB0$. The change in consumer surplus = P_nBCP_o. The change in producer surplus = $A0C - P_nBCP_o$. If the government kept the rice price at P_o, the total change would be an increase in producer surplus of $A0C$. Without the increased production due to research, Japan would have to import rice at a total foreign exchange cost of ACQ'_nQ_o to keep the price at P_o

Akino and Hayami provided formulas for estimating P_nBCP_o, ABC, $A0C$, and ACQ'_nQ_o:

$$(7)\quad P_nBCP_o = P_oQ_o\frac{K(1+e)}{e+n}\left[1 - \frac{\frac{1}{2}K(1+e)n}{e+n} - \tfrac{1}{2}K(1+e)n\right],$$

$$(8)\quad ABC = \tfrac{1}{2}P_oQ_o\frac{[K(1+e)]^2}{e+n},$$

$$(9)\quad A0C = KP_oQ_o,$$

$$(10)\quad ACQ'_nQ_o = (1+e)KP_oQ_o,$$

where K is the shift in the production function. The shift in the supply curve can be approximated by $(1 + e)$K.

Scobie and Posada employed the CS approach to study technical change in Colombian rice production. They considered the incidence of research costs and benefits among upland producers, irrigated producers, and consumers in various income groups. They concluded that consumers benefited most, producers suffered overall losses, but small producers lost the most.

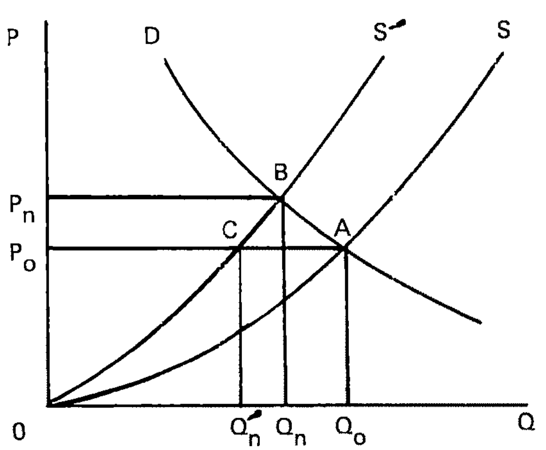

Figure 6. Rice supply shift due to breeding research

Duncan, using new pasture technologies, estimated benefits of research on an input into production of another commodity. The productivity increase shifts the derived demand curve for the input to the right. His expression for calculating social gain under specific assumptions (including a perfectly elastic demand curve) for the final product is $b(Pe^{-Q_1/b} - Pe^{-Q_2/b}) - P(Q_2 - Q_1)$, where b is the long-run price elasticity, P equals input price, Q_1 is old and Q_2 is new input quantity.

Ex post benefit-cost analyses which measure net benefits as increased production valued at constant prices also are in the CS classification (see, for example, Tosterud et al and Kislev and Hoffman). These studies implicitly postulate a perfectly elastic demand curve and a vertical supply curve.

Other studies using the CS approach include Barletta for corn and wheat in Mexico; Hines for corn in Peru; Hertford et al. for rice, soybeans, wheat, and cotton in Colombia; Flores-Moya, Evenson, and Hayami for rice in the Philippines; Nagy and Furtan for rapeseed in Canada; and Pinstrup-Andersen for effects of new agricultural technology on consumers at various income levels.

Lindner and Jarrett (1978) recognized that total benefits are influenced by the nature of the supply curve shift. They hypothesized that some innovations are more likely to generate divergent and others convergent supply shifts. Parallel shifts also are possible. Their reasoning focused on the effects of different types of innovations (biological, chemical, mechanical, and organizational) on average costs of marginal and inframarginal firms and the location of those firms on the industry supply curve.[1]

In their 1978 paper, Lindner and Jarrett provided a generalized formula for measuring research benefits. It avoids some of the biases arising from specific assumptions about supply shifts and elasticities. Utilizing figure 7,

[1] Lindner and Jarrett (1978) use the term inframarginal for the more profitable, lower cost firms. Rose, however, argues that the rent components in supply price makes it difficult to link given firms with particular points on the supply curve.

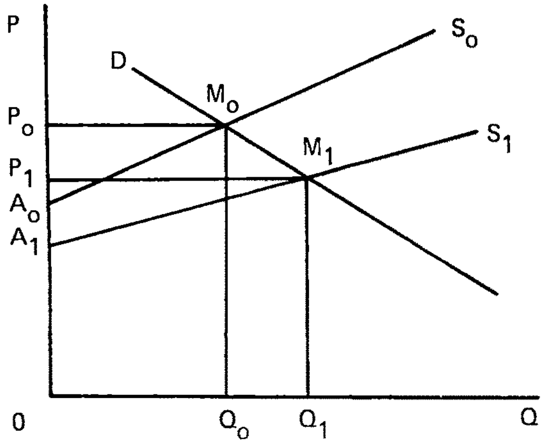

Figure 7. Lindner and Jarrett's research benefits

(12) change in total benefits
$$(A_1M_1M_oA_o) = \tfrac{1}{2}(P_oQ_1 - P_1Q_o + Q_oA_o - Q_1A_1),$$

(13) change in producer benefits
$$= \tfrac{1}{2}(Q_oA_o - Q_1A_1 - P_oQ_o + P_1Q_1), \text{ and}$$

(14) change in consumer benefits
$$= \tfrac{1}{2}(P_oQ_1 - P_1Q_o + P_oQ_o - P_1Q_1),$$

where P_o and Q_o are current price and quantity; $P_1 = P_o\left(1 - \frac{ke}{e+n}\right)$, $Q_1 = Q_o\left(1 + \frac{ken}{e+n}\right)$, where k is the absolute cost reduction at Q_o divided by P_o, e and n are the price elasticities of supply and demand, respectively (n is an absolute value); $A_1 = A_o(1 - K)$ for a proportional shift, $A_1 = (A_o - R)$, where R is the absolute reduction in average costs for all firms for a parallel shift, and $A_1 = A_o$ for a pivotal shift.

Lindner and Jarrett made a computational error which was subsequently pointed out by Rose and by Wise and Fell. Lindner and Jarrett (1980) point out that it arose because their equations apply only when the supply and demand curves are linear. Their calculation of P_1 and Q_1 from P_o and Q_o using a value of the local elasticity of supply implied by the chosen values of A_1 relative to P_1 and Q_1 violated the linearity assumption. Rose and Wise and Fell suggested inclusion of a kink in the S_1 curve directly below M_o to handle this problem (figure 8).

Rose proposed the following equation to estimate the change in total net social surplus:

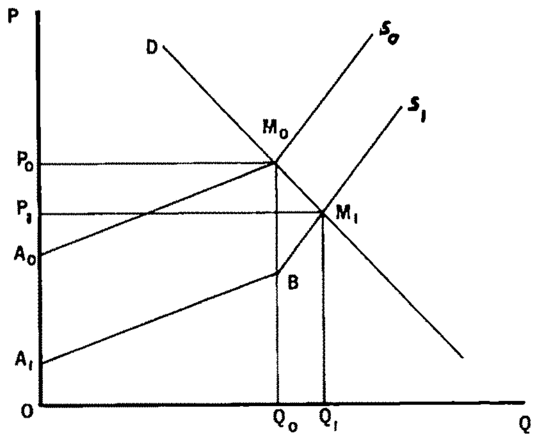

Figure 8. Rose's kinked supply curve

(15) change in total net social surplus
$$= \tfrac{1}{2}Q_o(KP_o + A_o - A_1) + \tfrac{1}{2}KP_o(Q_1 - Q_o),$$

where the first term represents the area $A_oM_oBA_1$ and the second term corresponds to M_oM_1B. For a parallel shift, this reduces to

(16) change in total net social surplus
$$= KP_oQ_o + \tfrac{1}{2}KP_o(Q_1 - Q_o).$$

For a pivotal shift it is

(17) change in total net social surplus
$$= \tfrac{1}{2}KP_oQ_o + \tfrac{1}{2}KP_o(Q_1 - Q_o).$$

The above discussion illustrates the extent to which CS studies have differed in specification of supply and demand functions and in the nature of supply function shifts. The various formulas presented here and others in the literature (for example, Barletta, Dalrymple, Ramalho de Castro, and Ardila) reflect these differences as well as alternative "K"-value derivations. The major differences and relative importance of shift, elasticity, and K-value assumptions underlying the Griliches (1958), Peterson (1967), Hertford and Schmitz, Akino and Hayami, Lindner and Jarrett (1978), and Rose formulas are summarized below.

Griliches assumed a parallel shift (horizontal or vertical); Peterson a proportional shift; Hertford and Schmitz a parallel shift; Akino and Hayami a pivotal shift; and Lindner and Jarrett and Rose four shifts. The nature of the shift assumed is very important. Divergent shifts result in fewer benefits to producers than either parallel or convergent shifts. Duncan and Tisdell have shown that producer returns will be negative when research leads to a divergent supply shift if demand is inelastic.

Lindner and Jarrett (1978) assert that these assumptions predetermined Akino and Hayami's conclusions about the distributional effects of Japanese rice breeding.

Griliches, Hertford and Schmitz, and Lindner and Jarrett assumed linear supply and demand curves. Peterson assumed a general specification. Akino and Hayami assumed constant elasticity supply and demand curves and Rose a linear kinked supply curve and a linear demand curve. These differences are less important than the type and magnitude of the supply shift.

The size of K is a major determinant of net benefits. In some cases K has been measured as an output effect (horizontal shift in the supply curve) and in others as a cost effect (vertical shift in the supply curve). The Hertford and Schmitz formula includes K as a horizontal shifter. Lindner and Jarrett (1978) and Rose used it as a vertical supply curve shifter. Akino and Hayami used K as a production function shifter. Peterson measured K as the proportional change in equilibrium quantity following the supply shift. This is less than Hertford and Schmitz's horizontal distance between the supply curves because of the fall in equilibrium price.

Equation (3), (18), (19), and (20) illustrate differences in the various total net social surplus formulas due to shift, functional form, and K values.

(18) Change in total net social surplus

$$= KP_1Q_1\left(\frac{1}{1+e} + \tfrac{1}{2}\frac{K}{e+n}\right).$$

Equation (18) was derived from Akino and Hayami's results, converting their production function shifter to a supply function shifter; P_1 and Q_1 are equilibrium quantity and price after a rightward supply shift. It is similar to equation (3) from Hertford and Schmitz. The additional e occurs because Akino and Hayami assumed a pivotal rather than parallel shift and a constant elasticity rather than linear supply curve. Had they assumed a linear supply curve, the first bracketed term would have equaled 1/2. Had they assumed linearity and a parallel shift, the two equations would be the same.

Equations (19) and (20) represent a parallel and a pivotal supply shift, respectively. They were derived from equations (16) and (17).

(19) Change in total net social surplus

$$= KP_oQ_o\left(1 + \tfrac{1}{2}\frac{ke}{e+n}\right).$$

(20) Change in total net social surplus

$$= KP_oQ_o\left(\tfrac{1}{2} + \tfrac{1}{2}\frac{ken}{e+n}\right).$$

These equations differ from (3) and (18) because P_o and Q_o are equilibrium price and quantity before the supply shift. Also, K is a proportional vertical shift in the supply curve. It could be converted to a horizontal shift since $K = ke$ (Lindner and Jarrett 1978).

Peterson's formula measures the area below the demand curve between the old and new equilibrium quantity to approximate the area between the supply curves. With a perfectly inelastic supply curve, it is identical to Hertford and Schmitz's equation (3). Griliches's formulas are special cases of equation (3) in the perfectly inelastic and of Lindner and Jarrett and Rose in the perfectly elastic supply case where new equilibrium price and quantity are used in the derivation of K and where $n = 1$.

The demand elasticity is also important because the more inelastic the demand curve, the more likely producers will lose following technical change. Also, if the supply elasticity is absolutely larger than the demand elasticity, consumers will tend to receive a larger share of the benefits than producers. In addition, those technologies which do not directly displace labor can do so indirectly as a result of a fall in the product price if the demand elasticity is low. Binswanger (1980) stressed the importance of general equilibrium effects on factoral income distribution. With the exception of a comment by Musalem, a reply by Ayer and Schuh (1974), and Just and Hueth's analysis of welfare effects of changes in economic surpluses in intermediate markets, general equilibrium effects have been ignored in CS evaluation. The basic flexibility of the CS approach can be a liability if underlying relationships and policies are not accurately mirrored in the analysis.

Production Function Approach

The basic model used in the production function (PF) approach has been

$$(21) \qquad Q = A \prod_{i=1}^{m} X_i^{\beta_i} \prod_{j=0}^{n} R_{t-j}^{\alpha_{t-j}} e^{v},$$

where Q is value of agricultural output, A is a shift factor, X_i is the ith conventional production input, R_{t-j} is expenditure on research (and extension) in the $t-j$th year, β_1 is the produc-

tion coefficient of the ith conventional input, α_{t-j} is the partial production coefficient of research (and extension) in the $t-j$th year, and u is a random error term.

A major source of variation among PF studies is the length and shape of the time lag reflecting the impact of research expenditures on output. Early studies, such as the pioneering work by Griliches (1964), used either a single year's lagged expenditure or a simple average of two previous years. In more recent U.S. studies, Evenson (1967), Fishelson, and Cline and Lu have used an inverted 'V' or 'U'-shaped distribution with a mean lag of six to seven years.

The model of equation (21) has been estimated mainly with cross-section data. Aggregate output was used by Griliches (1964) and Davis for the United States and Kahlon et al. for India. Others applied the model to commodity groups, for example, Peterson (1967), Bredahl and Peterson, and Norton. The latter two studies estimated the marginal internal rate of return (MIRR) to each of four commodity groups (cash grains, dairy, poultry, and livestock) and suggested how to increase the overall rate of return by reallocating research dollars from relatively low to relatively high payoff commodities.

Time-series studies often display an alternative specification:

$$P = AW^{\gamma}E^{\epsilon}\prod_{j=0}^{n} R_{t-j}^{\alpha_{t-j}}e^{v}, \tag{22}$$

where P is a productivity index of agricultural output; W is a weather index; E is a measure of the education level of farm workers; and γ, ϵ are productivity coefficients for the associated inputs.[2]

Most studies used a Cobb-Douglas specification. High intercorrelation problems with time-series data for conventional production inputs and the general lack of sufficient data for the important conventional inputs are major reasons for the use of a productivity index as the dependent variable.

Evenson (1967) first used this model to calculate the marginal product of research in the United States. Cline and Lu updated and refined Evenson's work for aggregate agricultural output and for ten production regions.

[2] Duality approaches using cost or profit functions provide alternative means of analyzing time-series data and have been used by Binswanger (1974), by Gollop and Jorgenson, and by others to analyze technical change. They have not been used as yet to calculate the payoff to agricultural research, however, and therefore are not discussed in this review.

The quality of various productivity indices is always in question. Evenson (1978) presented his own alternatives to officially published series of the U.S. aggregate index for 1870 to 1971, for regional indices for 1927 to 1971, and for individual state indices for 1949 to 1971. He analyzed the relationships between productivity and investment in (*a*) agricultural invention, (*b*) education, and (*c*) research and extension. Evenson divided the United States into geoclimatic regions and attempted to isolate spillover effects of research between different states. The research expenditure for each region was measured using commodity group research expenditures and output value proportions. His results showed a significant spillover effect between states. Evenson, Waggoner, and Ruttan also tested the impact of decentralizing scientists in substations. They found that decentralization of research within a state had a positive effect on productivity of state systems. Flores-Moya, Evenson, and Hayami; White and Havlicek; and others also analyzed the spillover of research among states, regions, and countries.

While all PF studies discussed above used research (and extension) expenditures as the measure of research, specific items included have varied considerably. For example, U.S. studies have ranged from that by Bredahl and Peterson which used only commodity-specific research expenditures by the state experiment stations to that by Cline and Lu which used total research and extension expenditures by experiment stations, the USDA, and the soil conservation service. Alternatively, Evenson and Kislev (1973, 1975) and Evenson (1974) used the number of scientific publications as a proxy for research. Evenson also separated expenditures into commodity-specific applied research and noncommodity-specific, agriculturally related basic research. Evenson and Binswanger included separate variables to measure effects of applied research and basic, science-oriented research.

The PF approach is useful for separating the production effects of research from those of education and conventional inputs among geographical areas. It also allows estimation of marginal as opposed to average rates of return. Difficulty in obtaining data on production inputs such as labor, machinery, and chemical applications by commodity remains a major limitation. Another is the uncertainty of projecting past rates of return into the future. Davis provided evidence that the production coefficient on the research variable in aggre-

gate agricultural production functions has declined since the 1950s, but remained stable since 1964. Finally, PF studies have treated research as an exogenous variable, a generally questionable assumption.

National Income Approach

Tweeten and Hines calculated how much lower the national income would be if the percentage of people on farms was still the same as in 1910 and the resulting additional farmers had the income of today's farmers instead of today's nonfarmers. They estimated the costs of public and private research, education, and federal programs. Then they calculated a benefit-cost ratio.

The larger the gap in earnings between farm and nonfarm workers and the higher the migration rate off the farm, the higher the returns to agricultural research and extension will be under this procedure. Marginal returns to research approach zero as the farm population stabilizes.

Nutritional Impact Approach

Pinstrup-Andersen, Londoño, and Hoover developed a procedure to estimate the nutritional implications of alternative commodity priorities in agricultural research policy. The model estimates the distribution of commodity supply increases among consumers, the related adjustments in total food consumption, and implications for calorie and protein nutrition.

Their model has two phases: (*a*) a price elasticity of demand matrix for various income strata and for the whole market and (*b*) the distribution of a hypothetical supply increase among income strata with resulting adjustments in consumption of other goods which impacts on calorie and protein nutrition.

Ex Ante Evaluation

Ex ante studies can be classified into four groups: (*a*) those using scoring models to rank research activities, (*b*) those employing benefit-cost analysis to establish rates of return to research, (*c*) those using simulation models, and (*d*) those using mathematical programming to select an optimal mix of research activities.

Scoring Models

In 1966 the National Association of State Universities and Land Grant Colleges-U.S. Department of Agriculture (NASULGC-USDA) published a study of U.S. agricultural and forestry research programs. A task force evaluated the strengths and weaknesses in the research program, identified future research problems, and recommended a level of public research investment for the next few years. A simple scoring model (SM) was used to determine the extent to which each research problem area met specified weighted criteria, although it was not employed on a systematic basis to arrive at the final estimate of research needs presented in the NASULGC-USDA study (Williamson). A major result of the study was the systematic classification of research problem areas now used in the USDA's Current Research Inventory System (CRIS).

Mahlstede, and Paulson and Kaldor reported on an SM program at Iowa State University "to ensure the greatest return for the research money spent at the experiment station" (Mahlstede, p. 327). First, administrators and department heads set goals of growth, equity, and security. Then research was classified into three major areas: commodity, resource, and agricultural management research. These areas were divided into nineteen subareas, and a panel was assigned to each to identify research alternatives and estimate the costs. Finally, a scoring procedure was used based on ten criteria including the probability of success. "The validity of the study rests heavily on the premise that scientists, through a systematic group effort, can predict, to some degree, the outcome of scientific inquiry and, thus, improve the basis for selecting research activities that will offer the highest return" (Mahlstede, p. 327).

Shumway and McCracken reported on a model used at the North Carolina Agricultural Experiment Station to determine the emphasis on each of several research problem areas (RPA) defined by the USDA CRIS classification. "The key actors in the study included the experiment station administration, two department head committees concerned with research planning and program implementation, twenty interdisciplinary faculty task forces, eighteen extramural scientist panels, and twenty-three academic departments" (Shumway and McCracken, p. 714). Each of the last three groups either rated or scored problem

areas or recommendations of other groups. A simple SM was used along with a Delphi procedure. Shumway and McCracken noted little consistency within or among groups of scorers. Schuh and Tollini point out that less attention was given to setting goals in the North Carolina procedure than was done in Iowa.

The NASULGC-USDA, Iowa, and North Carolina scoring models are conceptually simple but labor-intensive requiring frequent meetings among people for whom the opportunity cost of time is high. They have the advantage of incorporating benefits and goals that are difficult to quantify by most other procedures, but rankings are not independent of the rating scheme.

Ex Ante Benefit-Cost Approach

Several studies, conceptually analogous to *ex post* CS studies, calculated rates of return or benefit-cost (BC) ratios to proposed agricultural research. It is difficult to predict payoffs to individual projects because of the stochastic nature of research payoffs. Hence, a major difference among *ex ante* BC studies is the projection of yield increases or cost reductions.

Fishel (1971b) described a computerized model for collecting and processing information needed to evaluate research activities and to select an efficient allocation of resources. The model, called Minnesota Agricultural Research Resources Allocations Information (MARRAIS), involved three major steps: specification, estimation, and analysis. Project selection was left to the decision maker. Benefit-cost ratios, benefits minus costs, and internal rates of return were calculated by computer to obtain the needed information. Surveys were sent to numerous scientists in fields related to the proposed research project. They estimated average annual expenditures, time requirements, and technical feasibility. Subjective probability distributions of costs and values were generated for alternative levels of expenditures via a Monte-Carlo sampling procedure. MARRAIS is a sophisticated research evaluation model whose complexity may generate higher costs than simpler models.

Ramalho de Castro and Schuh presented a model focusing on growth and distributional effects of technical change along with direct and indirect effects of research. They set four goals for the research program, assumed a shift in the supply curve for various crops caused by technological change, compared distributional effects on consumers and producers, and examined implications of factor scarcity on desired research direction. They discussed effects of technological change in agriculture on the nonagricultural sector and the effects of economic policies on social benefits and costs of research. Their model minimizes the burden on scientists because it relies primarily on secondary data to project yield increases, adoption rates, and probabilities of success.

Taking a different approach, Easter and Norton used scientists' estimates of yield and cost effects of various research and expected adoption rates of new technologies to apply BC analysis to the land grant universities' 1978 USDA budget requests for soybean and corn production research. A 10% discount rate was applied, harvested acreage was held constant, and a specific set of prices was assumed. An important aspect of the analysis was the BC ratio's sensitivity to variations in probabilities of success, expected yield increases, product prices, and lags between research expenditures and availability of results. Sensitivity analysis provides decision makers with information on the importance of added precision in the evaluation. Effects on prices received by farmers, meat prices, and prices of fats and oils were estimated with impact multipliers from another study.

Araji, Sim, and Gardner conducted a similar type of evaluation for various commodities in the western United States. They conducted interviews with agricultural researchers and extension specialists to determine initiation and termination dates for research projects, probability of research success, probability and rate of adoption of research results (with and without extension), and the resources required to adopt and maintain the new technology. Yield, quality, and production cost changes resulting from the new technology were estimated, as were flows of benefits and costs, BC ratios, and internal rates of return for each project. They also estimated the productivity reduction which would result from eliminating maintenance research and used price flexibilities to determine effects on prices and consumer expenditures.

In another study, Eddleman (pp. 34–35) made use of multipliers from a national input-output analysis to measure secondary impacts of an increase in agricultural productivity.

Gross benefits were the changes in other sectors' output resulting from increased agricultural output. Net benefits were wage increases caused by expanded employment plus net profit gains in each sector.

The key to useful *ex ante* BC analysis is cooperation between physical and social scientists. If cooperation is present, rates and distributions of returns can be assessed relatively quickly. As with *ex post* CS analyses, assumptions made about demand and supply elasticities have important distributional implications.

Simulation Approach

Many researchers have constructed simulation (SI) models for research evaluation. Pinstrup-Andersen and Franklin described the basic components of an SI model for predicting relative contributions and costs of alternative research activities. Their first step is to establish overall goals. This is followed by an identification of changes in product supply, input demand, and farm consumption necessary to achieve those goals. Then research problems and alternative technologies to solve them are identified. The next step is to estimate the time, costs, and probabilities involved in research and farm adoption of the alternative technologies. Estimation of effects on farm consumption, product demand, and input-supply follows. Finally, specification of technology to be developed and scientists' working objectives are established. These steps require an extensive amount of data and estimation of numerous mathematical relationships.

Lu, Quance, and Liu formulated an SI model with R&E expenditures as a principal decision variable. Agricultural productivity changes were attributed to lagged values of production-oriented public agricultural R&E investments, changes in farmers' education, and weather. They used the model to project agricultural productivity growth under three alternative R&E investment growth rate scenarios. They also estimated BC ratios and internal rates of return to R&E investments. Knutson and Tweeten employed a similar model using the USDA-ESCS National-Interregional Projections (NIRAP) System to project farm output and prices resulting from projected changes in productivity.

White, Havlicek, and Otto analyzed investment patterns for agricultural productivity growth. They first estimated effects of research and extension on aggregate U.S. agricultural productivity with a time-series production function. Then they used control theory to determine optimal research expenditures for a given rate of increase in farm prices under selected conditions. Finally they examined effects of reduced research funding on consumer food expenditures and on taxes.

Scobie (1979) developed an SI model including a production function, supply and demand functions, and a discounted cash flow analysis to determine the optimal level of agricultural research investment. Output was assumed to grow at a given minimum rate without research. As research investment increased, the output growth rate increased but at a diminishing rate becoming asymptotic to a maximum rate. By varying assumptions about lags, functional forms, etc., he estimated annual research investments that would generate various internal rates of return.

SI models are more widely used for research evaluation in the private sector than for public agricultural research evaluation. Perhaps this is because the industrial research process is better understood and/or more tightly planned and controlled. Also, private research and development is likely to be less uncertain in its payoffs being more "applied" and less "basic" than public research.

Kislev and Rabiner feel that the research evaluator should try to identify and incorporate factors affecting process in given research lines. Using the Israeli dairy herd as an example, they built an SI model of a breeding program incorporating principles of quantitative genetics, decision variables, and natural constraints to selection. They defined an ideal breeding model and attempted to explain the gap between the real breeding program and the ideal system. This information is useful for *ex ante* evaluation because it provides a guide to constraining factors in research.

SI models are flexible. They can be used to estimate (*a*) optimal levels of research at a national, commodity, or program level, and (*b*) effects of research on prices, income, employment, or other parameters. Unless the models are extremely naive, however, their construction requires much time and information.

Mathematical Programming Approach

Two studies have used mathematical programming (MP) to determine optimal allocation of a given research budget. Russell devel-

oped a model called the Resource Allocation System for Agricultural Research (RASAR) to assist in selecting a portfolio of government-sponsored agricultural research projects in the United Kingdom. He first established an overall goal of outputs "needed to permit the attainment of an ideal state for social welfare" (p. 34). Three dimensions of this goal were identified (consumption, security, and equity) along with nine aspects of these dimensions and a rating system. He used an MP model to maximize utility from the research program. It provided information on (*a*) the set of projects in the research program, (*b*) financing for each project, (*c*) the marginal utility derived from investing in extra units of resources for the program and each project, and (*d*) the sensitivity of project selection to varying weights on goals. The system was tested on a group of projects at Scottish research establishments.

Cartwright developed a model focusing on research resource allocation within an agricultural economics department. He analyzed the problems of choosing major research areas and specific research jobs. To analyze the former, he developed a nonlinear integer programming model which used a staff preference function and information on (*a*) researcher time, (*b*) funds that new research areas would bring into the department, and (*c*) new staff positions that would be created. The job selection model also assumed a centralized decision process and required similar information.

A major difficulty in using MP to guide research resource allocation is that a preference function must be specified. Only this and the SM approaches require elicitation of decision makers' preferences.

Conclusions and Implications

Optimal research resource allocation depends on the market for research results and technological characteristics of the process itself. Private firms underinvest from society's viewpoint in many types of agricultural research because knowledge generated cannot be fully appropriated by the firm producing it. Research, especially basic research, is inherently risky. Governments recognize this and invest substantially in agricultural research.

Many approaches are used to evaluate public research investments. No one approach is superior in all situations. While it is possible to develop a theoretical model to incorporate all relevant research evaluation issues, such a model would consume enormous resources and time. Therefore, it is useful to compare approaches, drawing conclusions about their strengths, weaknesses, and ability to answer different questions. Several relevant comparisons are shown in table 1.

Goals must be established before research priorities can be set. Goals exist at various levels and often conflict. A single research project usually bears on multiple goals. The more normative the study, the more important it is to elicit and quantify trade-offs among goals of relevant decision makers. For this reason, SM and MP approaches usually involve some elicitation of goals. All research evaluation studies, however, deal implicitly, if not explicitly, with goals. Many CS and *ex ante* BC studies, recognizing that equity may be an important goal, have examined distributional effects on consumers and/or producers. The CS and *ex ante* BC approaches can most easily provide this information.

The PF technique is best for examining effects of research on the relative productivity and income shares of input categories. Few studies have accounted for secondary impacts such as displaced resources, environmental effects, or regional impacts, but CS, *ex ante* BC, SM, and SI approaches can do this.

Economic policies affect returns to agricultural research. Theoretically, policy can be included in every one of the approaches. The PF approach does it implicitly, while the others may do it explicitly.

It is evident from table 1 that several alternative techniques can be used to answer given questions. The choice of which to employ will be affected by their relative time costs. A quick look at cost characteristics, table 1, indicates why CS, PF, and *ex ante* BC approaches are the most widely used quantitative agricultural evaluation tools. Time costs partly explain why nonquantitative, completely subjective evaluation is so common.

Can more quantitative analysis of benefits and costs improve the decision-making process and, if it can, is it worth the cost? Some argue that there is so much serendipity involved in research, that *ex ante* evaluation of research resource allocation is meaningless. Clearly, there is the danger of dampened incentives and creativity if research is "overmanaged." It is difficult to predict high payoff projects using any of the techniques in table 1, especially in basic research where relevance and value may not be readily apparent. *Ex post* rates of return estimated by the CS and

Table 1. Comparison among Major Agricultural Research Evaluation Techniques

[a] CS is consumer-producer surplus approach; PF is production function approach.
[b] SM is scoring model approach; BC is *ex ante* benefit cost approach; SI is simulation model approach; MP is mathematical programming approach.

PF approaches document a general underinvestment in agricultural research. These results can be and have been used to support state and national budget requests.

These techniques vary in needed data. The PF technique typically requires much data, usually secondary. On the other hand, the SM requires little, but costly, primary data.

Few studies have measured the value of maintenance research. The maintenance of crop and livestock yields over time probably reflects a larger proportion of total research benefits and could be measured most easily with the CS approach.

Evaluation of research may occur at the aggregate, commodity, and project levels. The PF approach has little value at the project level where SM and MP approaches are potentially most applicable. A major problem in evaluating noncommodity research is defining and measuring the output. In general, the output is information rather than improved input

quality. Potential exists for using CS and *ex ante* BC analyses to quantify returns to such research.

Uncertainty can be incorporated, but it considerably complicates the PF approach. Time lags can be considered, although their statistical estimation is feasible only with the PF approach. No approach permits accurate measurement of public-private or the research-extension interactions. Research spillover from one area to another can be quantified with production functions and with some types of simulation.

Not all approaches involve rate-of-return calculations. A marginal rate of return can be readily calculated using a production function, while CS and *ex ante* BC analyses usually provide average rates of return. Being statistical methods, the PF and SI approaches can hold nonresearch inputs constant in an analysis.

SM, SI, and *ex ante* BC models can be used to identify and quantify factors affecting progress in given research lines. None do a good job evaluating basic research.

A rich set of evaluative procedures have been developed, but additional work is needed. Three areas in need of further methodological work are (*a*) the evaluation of noncommodity research, (*b*) analysis of factors affecting progress in given research lines, and (*c*) the study of private-public interaction in agricultural research, including transmission of research results to farmers.[3]

Editor's Note

Two lines of type were inadvertently omitted from the article, "Farmers' Credit Risks and Liquidity Management," written by Barry, Baker, and Sanint in the May 1981 issue of the *Journal*. The omission occurred on page 219, 5 lines above equation (13a), where two lines of type are repeated. The full sentence, which should replace the incorrectly repeated lines and conclude the paragraph, is: "The value of $\hat{\sigma}_{ri}$, then, is .00013, which requires a higher covariance in order for debt use in expression (11) to exceed its value in (7)." The editors apologize.

Notes

Impact of Corn Prices on Slaughter Beef Composition and Prices

Enrique Ospina and C. Richard Shumway

The purpose of this paper is to examine the relationships between feed grain prices and the beef product mix. An annual econometric model of the U.S. livestock industry (Ospina and Shumway 1979, 1980) is used to evaluate the impact of corn price changes on the composition of slaughter beef supplies and the relative prices of the quality categories by analyzing the reduced-form dynamic multipliers.

The structural form of this model disaggregates beef demand among three quality components (U.S. Department of Agriculture [USDA] grades prime and choice, good, and standard-and-lower, labeled for convenience as choice, good, and utility, respectively).[1] Supplies are disaggregated among the same quality categories and also among sex categories (steers, heifers, and breeding herd culls). Simultaneity is modeled in the demand, supply, and inventory decisions. Pork and broiler functions are incorporated. The separate effects of current and expected prices on supplies are differentiated, and feed grain prices are assumed to be exogenous.[2] All functions are linear, and the analysis is at the carcass level.

Three changes were made in the earlier model, and its parameters are reestimated (Ospina and Shumway 1981). The changes include the following. (*a*) Three subsequent years of data are added, thus making a twenty-three-year data period, 1956–78. (*b*) Because important changes in USDA beef grades took place in early 1976 which affected the choice and good grade definitions (Nelson), an intercept dummy variable is added to these supply and demand equations to account for its impact. (*c*) A relatively minor change is made in the disaggregation of data among the good and utility beef categories.[3]

The change in USDA grade definitions significantly increases the supply of choice beef and decreases the supply of good beef. The estimated parameters of the grade change dummy variables have expected signs and low standard errors in five of the six structural equations to which they are added.

Several substantive differences from the earlier estimation occur in the magnitudes of individual parameters because of the additional data and other modifications. However, parameter signs and the earlier general conclusions are stable. In particular, the aggregate short-run beef supply response remains positive (this finding contrasts with the conclusions of some earlier writers, e.g., Reutlinger, Tryfos), and the supply response to a 1% decrease in corn price remains greater than the response to a 1% increase in beef prices. At 1978 prices, the elasticities of beef supply are estimated to be -0.23 with respect to corn price and $+0.15$ with respect to average beef price. These estimates are similar to our earlier estimates of -0.25 and $+0.14$, respectively, at mean 1956–75 prices.

Reduced-Form Model

The reduced-form model was derived and the stability conditions of the model determined (Theil and Boot, p. 144). The model is stable; the absolute

Enrique Ospina, formerly an agricultural economist at Winrock International, and C. Richard Shumway are, respectively, visiting assistant professor and professor of agricultural economics, Texas A&M University.

Texas Agricultural Experiment Station Technical Article No. 16838. This paper is a result of research contributing to Western Project W-145.

The authors acknowledge with appreciation the constructive comments on earlier drafts by Allen Paul, Jean-Paul Chavas, R. O. Wheeler, Jon Brandt, and an anonymous reviewer.

[1] Many models, varying in scope and refinement, are available in the literature. Reutlinger disaggregated beef production data among sex categories (steers, heifers, cows, and bulls). Langemeier and Thompson, Freebairn and Rausser, Folwell and Shapouri, Shuib and Menkhaus, and Arzac and Wilkinson disaggregated by quality into fed and nonfed beef groups. All have incorporated grain prices in the fed beef supply function, but the relation of nonfed beef supplies and grain prices generally has not been explored.

[2] While supply and demand functions are assumed to depend on current prices, inventories are functions of expected prices. Proxies for expected prices in the model include (*a*) lagged prices, and (*b*) prices predicted by polynomial distributed lag model, both consistent with the period of decision making (Ospina and Shumway 1979, pp. 49–50).

[3] In the data for the original model, nongraded standard beef was assumed to be the same percentage of nongraded beef as graded standard beef was of graded beef (Ospina and Shumway 1980, pp. 23–24). Because this appears to underestimate the quantity of slaughter beef that would have graded standard or lower, if all beef were graded, the data are adjusted for this paper by assuming the same standard-to-good ratio in both graded and nongraded supplies. This results in somewhat larger estimates of utility beef, but only a small percent reduction in good beef. Functional forms, underlying assumptions, and variable definitions remain as in the original model. The data sources are the same as previously used (U.S. Department of Agriculture 1965–79a, b, c, 1979; U.S. Department of Commerce 1971, 1971–79).

value of each of the characteristic roots (two real roots, .39 and −.69) of the reduced-form coefficient matrix of the lagged endogenous variables is less than unity. The system exhibits dampening oscillations, and the paths of the endogenous variables are convergent.

Corn Price Multipliers

The dynamic multipliers were estimated following Theil and Boot. Table 1 reports estimates of the effects of an increase of $1 per bushel in the price of corn on beef quantities supplied and prices.

The impact multipliers (no lag) indicate that the immediate (current year) total effect of an increase in the price of corn is a reduction in choice beef supplies and increases in good beef and in domestic utility beef supplies. Total slaughter beef supplies decrease. Higher corn price results in increased choice and good beef prices, decreased utility beef price, and increased average beef price.

The delayed multipliers, presented in table 1 for each of six years following a sustained corn price change, depict the dynamic features of the model. Choice beef supplies increase in the next two years after a corn price increase, thus partially offsetting the substantial reduction that occurs immediately. Subsequent differential changes alternate in sign and decrease in absolute magnitude. The initial increase in good beef supplies is further augmented by an increase the year after the corn price increase. Subsequent delayed multipliers move in the opposite direction of choice beef supplies; the absolute value of the multiplier is highest in the second year. For the supply of domestic utility beef, the delayed multiplier has a positive sign the first two years after the corn price increase, and then it alternates in sign each year thereafter. The magnitude of utility beef supply response in the year after the corn price change is more than ten times greater than in the year of the change. This reflects a substantial liquidation of the breeding herd as initial changes in corn price are translated into sustained changes in price expectations. The delayed multiplier for total beef supplies is positive in the first year after the corn price increase, then alternates in sign and decreases in magnitude each year thereafter. The immediate directional movement in total beef supplies is caused primarily by the large changes in choice beef, next, to changes in utility beef, and, subsequently, to changes in the good beef category.

The delayed multipliers for the price of each beef category are negative during the first two years after the corn price increase and positive in the third year. Then they alternate in sign thereafter, always decreasing in magnitude. The strength of the effect of a corn price change on utility beef price may at first seem somewhat surprising since corn price does not enter the structural equation because not much grain is fed to cows prior to slaughtering. This result, however, underscores the effect of corn price on beef breeding herd buildup and liquidation.

The equilibrium (or cumulative) multiplier resulting from a sustained corn price increase implies a large decrease in choice beef supplies, a minor increase in good beef supplies, and a substantial increase in utility beef supplies. The absolute magnitude of the change in choice beef supplies is double that in the other two categories combined. Thus, there is a decrease in overall beef slaughter. The equilibrium multipliers for beef prices indicate an increase in choice beef prices, and a decrease in good, utility, and average beef prices. By far the greatest price change is for utility beef.

Multiplier Effects on 1978 Levels

Choice beef supplies in 1978 were 12,670 million pounds, good beef supplies were 6,578 million pounds, and domestic utility beef supplies were 4,835 million pounds, representing 52.6%, 27.3%, and 20.1%, respectively, of total domestic slaughter beef supplies. Average corn price for 1978 was $2.31 per bushel. An increase of $1 per bushel of corn (43% of 1978 price) reduces current-year choice beef supplies by 21% (to 10,060 million lbs.); it increases good beef supplies and utility beef supplies by 1.4% and 1.9% each (to 6,670 and 4,926

Table 1. Mean Estimates of Multipliers for an Increase of $1 per Bushel in Corn Price

Years	Beef Quantity				Beef Price

6	23,893.6	−33,882.9	4,885.0	−5,104.3	−.07	−.19	−.41	−.19
Cumulative	−2,306,529.0	131,138.0	1,022,311.0	−1,153,080.0	2.31	−1.51	−14.54	−2.93

million lbs., respectively). Total beef supplies decrease by 10%. The new proportions are 46.5%, 30.8%, and 22.7% for choice, good, and utility beef supplies, respectively. The choice-good beef quantity ratio declines from 1.93 to 1.51, and the choice-utility beef quantity ratio declines from 2.62 to 2.04.

An increase in corn price that is sustained long enough to attain a new equilibrium reduces choice beef supplies by 18% (to 10,363 million lbs.), increases good beef supplies by 2% (to 6,709 million lbs.), and increases utility beef supplies by 21% (to 5,857 million lbs.). Total beef supplies decrease by 5%. The new proportions are 45.2%, 29.3%, and 25.5% for choice, good, and utility beef supplies, respectively. The choice-good beef quantity ratio is 1.54, and the choice-utility beef quantity ratio is 1.77.

Prices in 1978 were $79.78, $75.47, and $65.37 per hundredweight for choice, good, and utility beef, respectively. Following an increase in corn price of $1 per bushel, current-year choice beef price increases by an estimated 7.5% (to $85.75/cwt.), good beef price increases by 3.3% (to $77.95/cwt.), and utility beef price declines by 11.7% (to $57.73/cwt.). The choice-good beef price ratio increases only a little, from 1.06 to 1.10, and the choice-utility price ratio increases from 1.22 to 1.49.

With sustained increase in corn price, choice beef price increases by 2.9% (to $82.09/cwt.), good beef price declines by 2% (to $73.96/cwt.), and utility beef price declines by 22.2% (to $50.82/cwt.). The new choice-good price ratio is 1.11, and the choice-utility price ratio is 1.61.

Elasticities

Total elasticities of beef quantities and prices with respect to corn price are in table 2. These elasticities are derived from the reduced-form equations at 1978 variable levels. They are measures of the general equilibrium elasticities after either all current year or all cumulative adjustments in other variables have been accounted for. Consequently, they differ from partial supply elasticities based on the structural model parameters. Some of the total elasticities for a sustained change in corn price also differ substantially from the total elasticities for a current year change in corn price. Most notable are the elasticities for utility beef quantity and price. This difference occurs because lagged prices are used as proxies for expected prices in the breeding herd inventory demand equation. Thus, the major change in slaughter cow supplies is estimated to occur in the year after the initial change in corn price.

If corn price were to increase 10%, a very small (.4%) current year increase in lean (good and utility) beef supplies would result. It would be accompanied by a substantial (4.8%) decrease in choice beef supplies and an important reduction (2.4%) in the total quantity of beef marketed. Price of utility beef drops considerably (2.7%) but the average price of all beef increases a little (.5%).

A sustained 10% increase in corn price has a major impact on the supply of lean beef (4.9% increase in utility and .5% increase in good beef). The 4.2% decrease in choice beef results in a 1.1% total decrease in beef marketed. Only the price of choice beef goes up (.7%). The price of utility beef drops 5.1% and the average price of all beef goes down .9%. Thus, sustained increases in the price of grain have important implications on the quantity of lean beef marketed, the ratio of choice to lean beef, and the price of utility beef.

Table 2. Total Elasticities of Domestic Slaughter Beef Quantity and Price

	Elasticity with Respect to Corn Price Change[a]	
Category	Current Year	When Sustained
Choice beef quantity	−.48	−.42
Good beef quantity	.03	.05
Utility beef quantity	.04	.49
All beef quantity	−.24	−.11
Choice beef price	.17	.07
Good beef price	.08	−.05
Utility beef price	−.27	−.51
All beef price	.05	−.09

[a] Computed at 1978 levels.

Conclusions

The impact of corn price on composition and prices of slaughter beef was examined from the reduced form of an annual disaggregated econometric model of the U.S. livestock industry. The quality composition and relative prices of slaughter beef categories change dramatically in response to corn price changes. This is true both of current year and long-term effects. The greatest current year impacts of an increase in corn price are decreases in choice beef slaughter and utility beef price. In the long run, a sustained corn price increase will have its greatest influence by decreasing choice beef slaughter, increasing utility beef slaughter, and decreasing utility beef price. The contention that higher grain prices will eventually mean higher beef prices is supported by this analysis only with respect to choice beef. Average beef price actually declines because of a major reduction in quality of beef marketed. Not only are choice beef supplies substantially reduced but lean beef production is increased, and price differentials are widened. Thus, the change in perceived quality is amplified.

Price Variation in Direct and Terminal Markets for Cattle and Hogs: An Illinois Case

Mahlon G. Lang and Franco Rosa

The increasing importance of direct, as opposed to terminal, livestock markets is well-known. During the 1961–78 period, the nation's share of cattle purchased through direct channels rose from 38% to 73.4%, and the nation's share of hogs sold directly rose from 59.6% to 73.8%.

Pecuniary advantages of direct marketing explain this trend. Changes in the structure of the livestock production and slaughter industries often permit traders to reduce procurement costs through direct purchases. Among these changes are the decentralization of packing firms and the emergence of larger production units. But there is concern regarding the price discovery implications of the trend to direct marketing. This is reflected in research on marketing alternatives for agriculture and in concern about "thin" markets (Hayenga).

The marketing alternatives and thin markets literature is ultimately concerned with the performance consequences of vertical coordination alternatives. While that literature identifies several performance dimensions by which to compare these alternatives, the development of operational performance measures has been slow.

Day-to-day price variation was used to compare performance in Illinois direct and terminal markets for slaughter cattle and hogs. This involved (*a*) the development of a working hypothesis, (*b*) the collection of data with which to test the hypothesis, and (*c*) the analysis and interpretation of these data.

Theory and Hypothesis

In a perfect market, the equilibrium price of a given commodity at spatially separated points will, *ceteris paribus,* differ at most by transfer costs (Bressler and King, p. 89). This assumes (*a*) perfect knowledge by buyers and sellers, (*b*) rational behavior, and (*c*) free entry in all directions (Bressler and King, p. 84). Under these conditions, one also would expect equal day-to-day price variance in spatially separated markets.

Mahlon G. Lang is an assistant professor, and Franco Rosa is a former student in the Department of Agricultural Economics at Purdue University.

Journal Paper No. 8238 of the Purdue University Agricultural Experiment Station.

The authors express their gratitude to E. M. Babb, J. A. Brandt, L. F. Schrader, and two anonymous reviewers for their helpful comments.

But there are two reasons to expect that observed price variance is greater in direct markets than in terminal markets. These involve market structure and price-reporting practices.

First, market information is more complete in terminal markets than in direct markets. Since terminal market trading is geographically concentrated, price discovery in a given terminal market transaction may be directly affected by several well-informed packer buyers and several commission agents who, as market specialists, represent producers.

In contrast, direct market transactions are geographically diffused. Transactions are consummated at many packing houses, country buying points and individual feedlots. An individual transaction may be directly affected by only one buyer and one seller. While packer buyers may be well-informed, the producer, who is not a market specialist, generally cannot bring as much market information to a direct market transaction as can a commission agent in a terminal market.

Second, direct-market price reports are based on sampling and the reporter's judgement. But terminal-market price reports are based on a summary of virtually all trading at the terminal. Hence, the sampling error is greater in direct market price reports than in terminal reports.

These observations are the basis for the hypothesis that observed day-to-day price variation is greater in direct than in terminal markets. This hypothesis was explored by testing formal hypotheses of equal statistical variance.

Method

Data were secured through the Illinois Federal-State Market News Office. The data include daily prices paid in 1976 to farmers in the Illinois direct and terminal markets for nine classes of slaughter cattle and seven classes of slaughter hogs. Terminal market data reflect trading at Joliet, Illinois. The direct market data represent the market reporters' summary of direct purchases by seven packers and seven order buyers.

The raw data were reported as a daily range of prices for each class of livestock. The midpoint of each reported range was used in the analysis. The midpoint would not be a maximum likelihood price estimator if there were a reporting bias. However,

since variance is independent of scale, this would not affect the measure of day-to-day price variance if one assumes that any reporting bias is consistent.

The data were subdivided by month to reduce the influence of seasonal price variation. Then, to eliminate the effects of within-month trends, a quadratic trend line was estimated for each month, for both markets and for both classes of livestock. In more than two-thirds of the cases, an F-test for the presence of trend was significant at the .05 level.

Results

For cattle, well over half of the monthly comparisons showed greater price variance in direct markets than in terminal markets. For hogs, the reverse was true. While statistically significant, we judge that these differences are not economically significant.

Price Variance around Trend: Cattle

Cattle price data were sufficient to compute 83 direct and terminal market variance pairs. Ratios of the sample variance pairs were used to compute F-statistics with which to test the hypothesis of equal variance.

As table 1 shows, the hypothesis of equal variance was rejected nineteen times at the .10 level in favor of the alternative hypothesis of greater direct market price variance. The same hypothesis was rejected twelve times at the .05 level and two times at the .01 level. In four cases, the hypothesis was rejected in favor of the hypothesis that price variance in terminal markets is greater.

Price Variance around Trend: Hogs

Hog price data were adequate to secure eighty-four direct and terminal market variance pairs. Table 2 shows that the hypothesis of equal variance was rejected twenty-five times at the .10 level, nineteen times at the .05 level, and eleven times at the .01 level. All cases indicated greater price variance in the terminal market.

But of the twenty-five tests in which the equal variance hypothesis was rejected, eighteen were among the two heaviest (330–500 lb.) classes. For this reason, the sixty variance pairs representing the five lighter classes were separated for further analysis.

Further Analysis

The individual tests of equal variance showed a higher variance in the direct cattle market for fifty-six of eighty-three variance pairs. For hogs, forty-seven of sixty variance pairs showed a higher variance in the terminal market.

But, if price variance in direct and terminal markets were equal, one would expect one-half of the variance pairs to show greater variance in the direct market and one-half to show greater variance in the terminal market. To determine whether the sample proportions could have been drawn from such a population, an F-statistic (Yamane, pp. 660–4) was used to test this hypothesis. For both cattle and hog data, the test was rejected at the .01 level. These results are consistent with those of the previous analysis.

Economic Significance

For the period analyzed, the economic significance of these differences is negligible. This is demonstrated by drawing upon extreme cases of statistically different price variation.[1] Producers selling 1,000-pound choice steers in February direct markets would have had one chance in seven of receiving up to 30¢ per hundredweight less than their counterparts in terminal markets. Producers of 200-pound 1- and 2-grade hogs, by selling in January terminal markets, would have run one chance in twelve of receiving up to 19¢ per hundredweight less than producers selling in direct markets. Further, assuming normally distributed price variation, both cattle and hog producers would have had the same chances of gaining up to 30¢ per hundredweight (cattle) and 19¢ per hundredweight (hogs) by dealing in the markets where price variation was greater.

Because the potential losses from selling in the more variable markets were well under 1% of livestock prices at the time of this study, only the extreme risk averter would have changed markets on the basis of these findings. If the economic consequences of selling in the market with a greater price variance were more severe, producers might devote more effort to assembling market intelligence. Their resulting behavior would then drive price variation in the two markets closer together.

Interpretation: An Alternative Hypothesis

These mixed findings require further study. There is one alternative hypothesis which, while conjectural, is based upon discussions with livestock marketing specialists and market reporters who were informed of these findings.

Livestock buyers for a given packer are stationed both at country buying points and terminal markets. The buyers communicate with each other daily. In contrast, all but the most sophisticated livestock producers have less access to market information. This information asymmetry, along with the buying practices discussed below, may explain the mixed statistical results.

On a given day, the aggressiveness with which

[1] These calculations are too extensive for presentation here. Interested persons may write to the authors.

buyers must bid to secure needed livestock supplies depends on their estimates of availability. A buyer procuring livestock in two or more locations logically uses the most active location to guide bidding at other locations.

For cattle buyers, terminal yards remain an important single source of supply even though, in total, more of their purchases are made directly at several buying points. They, therefore, use terminal market supplies to guide bidding in direct country buying.

Direct market trading for hogs differs from that for cattle. Direct sales by hog producers are more likely to move to concentrated buying points than directly to slaughter plants. Thus, hog buyers use deliveries to direct buying points to guide their bidding in the terminal yard.

These buying practices may explain differences in price variation in markets for cattle and hogs. When livestock deliveries are low at the buyer's single most important source of supply, aggressive bidding will not bring forth greater supplies at that location on a given day. But at diffused or residual buying points, slightly more aggressive bidding may be effective and probably would cost less on the margin. Alternatively, when supplies are ample at the main source of supply, weaker bidding at residual buying points may occur, securing needed supplies at lower prices.

Since the terminal market is the most important single supply point for cattle, cattle price variation is greater in direct markets. However, because direct country buying points are the most important single source of supply for hog buyers, hog price variation is greater in the terminal market.

This phenomenon would not be expected in the absence of information asymmetry. Sellers possessing information parity with buyers would, with knowledge of supply conditions at major purchase points, anticipate the buyers' pricing moves and sell where more aggressive bidding is anticipated.

A Disaggregated Analysis of Corn Acreage Response in Kentucky

Michael R. Reed and Steven K. Riggins

One of the most commonly researched areas in agricultural economics is acreage supply analysis. The factors which determine the amount of land farmers plant to various crops are vitally important to farm policy decision makers. The trend in this area of research is clearly toward more disaggregated acreage supply functions. Recent studies by Whittaker and Bancroft, and Morzuch, Weaver, and Helmberger are examples of acreage supply analyses using data on a state-by-state basis. Morzuch, Weaver, and Helmberger argue that "spatial heterogeneity and the opportunity for measuring variables with greater precision might well make disaggregation at least to the state level worth the extra costs of data collection and analysis" (p. 37).

The purpose of this paper is to investigate the gain in explanatory power which can accrue to acreage supply functions for corn when data is disaggregated beyond the state level. This disaggregation not only allows for greater accuracy in the measurement of variables, but also allows the production function to vary by area. A disaggregated analysis should be particularly appropriate for states with a wide range in productivity of farm land.

The approach used in this study is to fit an acreage supply function for corn with substate data, then compare the results with the results of an acreage supply function using statewide data.

Model Specification and Data

The acreage supply for corn specified in this study is

(1) $AC_{it} = f(PC_{it-1}, PS_{it-1}, AC_{it-1}, GP_t)\ i = 1, \ldots, 14,$

where AC_{it} is acres of corn planted in area i in year t (in 1,000 acres), PC_{it-1} is the relative price of corn in area i in year $t-1$, PS_{it-1} is the relative price of soybeans in area i in year $t-1$, AC_{it-1} is acres of corn planted in area i in year $t-1$ (in 1,000 acres), and GP_t is a variable to measure government programs in year t. Relative prices are output prices divided by a fertilizer price. Fertilizer prices are used as a measure of input prices because they are readily available and account for a large proportion of production costs.

We have assumed, using this specification, that producers operate in a perfectly competitive market, making planting decisions in order to maximize expected profits. Lagged relative prices are used to measure the expected relative price in year t. The major crop which competes with corn for acreage in Kentucky is soybeans, so the relative price of soybeans in year $t-1$ was included in the corn acreage function. In addition, it is assumed that producers do not react immediately to changes in factors which influence acreage decisions due to the cost of change and inertia. For this reason, lagged corn acreage is also included as an explanatory variable.

Numerous variable definitions were tried in the model structure to capture the effects of government programs for corn. The results of the various variable definitions will be discussed in the results section. Earlier model specifications had futures prices around planting time in place of lagged prices to measure the price producers expect for corn and soybeans. These futures prices were adjusted using the previous year's basis when such data was available. The results of these earlier specifications were judged inferior to the results reported on the basis of t-values and R^2 values.

The model was applied to acres devoted to corn in Kentucky for the 1960–79 period. The state of Kentucky has a wide variety of agricultural settings. The western section of Kentucky is the cash grain area of the state. Farms are similar to Corn Belt farms, except on a smaller scale. The middle section of Kentucky has been dominated by cow-calf operations for many years. However, the production of grains as a cash crop has increased in recent years. The eastern section of the state is characterized by very limited, subsistence-type farming because of topography.

For the analysis of corn acreage response, Kentucky was broken down into fourteen areas. These are the official extension areas of the state. Areas 1 through 6 are Western Kentucky, the predominantly cash grain area; areas 7 through 10 are Central Kentucky, the areas characterized by cow-calf operations; and areas 11 through 14 are Eastern Kentucky, where farming is rather limited.

Individual area prices for corn and soybeans

Michael R. Reed and Steven K. Riggins are, respectively, assistant professor and assistant Extension professor of agricultural economics at the University of Kentucky.

The authors would like to thank C. Richard Shumway and two anonymous *Journal* reviewers for helpful comments.

were available for areas 1 through 6 and area 8; prices in other areas were assumed to be the statewide average. Area prices for corn and soybeans were the average price received by farmers in the farm analysis program of Kentucky and were collected from the Kentucky Cooperative Extension Service.[1] Data on the statewide Kentucky price of corn and soybeans, acreage, and fertilizer costs were gathered from the Kentucky Crop Reporting Service. Fertilizer prices for corn and soybeans were calculated assuming that nitrogen, phosphorus, and potash were applied in a 2:1:1 ratio for corn and a 0:1:1 ratio for soybeans. The respective ratios were used as weights to form the fertilizer prices. The data on acreage were acres harvested rather than acres planted, because a consistent series on acres planted was unavailable. Data on all variables used to measure the government program came from the U.S. Department of Agriculture. Crop prices were in dollars per bushel and fertilizer prices were in dollars per ton. All data were on an annual basis.

Results

As stated earlier, numerous variable definitions for the government program for corn were attempted. The price support, the set-aside payment, and the target rate were used to measure the government program. However, the minimum diversion required to qualify for the price support payment (in percentage terms) was found to perform the best for areas 1 through 8; and the maximum diversion allowed under the price support program (in percentage terms) was found to perform the best for areas 9 through 14. Producers in the less productive areas of Kentucky seem to be more concerned with how much acreage they can divert. This is probably caused by the fact that there are many more part-time farmers in the less productive areas.

Equation (1) was estimated using the seemingly unrelated regressions (SUR) model for each of the areas. This method was used because it was felt that error terms between area equations could be correlated because of omitted variables or other reasons. The SUR provides estimates of parameters which are asymptotically more efficient than ordinary least squares by using the correlation between contemporaneous disturbances of the area equations. All functional forms were linear.

Table 1 shows the coefficient estimates, standard errors, mean elasticities, and R^2 values of equation (1) for the fourteen areas. The R^2 values were obtained using ordinary least squares. The coefficient for the relative price of corn was significantly different from zero in five of the fourteen equations. The elasticity of corn acreage with respect to the relative price of corn ranged from .34 to .56 in the short run and from .93 to 2.07 in the long run.[2] These elasticity estimates are much larger than Whittaker and Bancroft's elasticity estimates of .22 for the entire United States. However, their model used the price of corn rather than the relative price of corn, which was used in this model. Also, Kentucky can easily turn some land used for pasture into cropland if crop prices are favorable. This is not generally true of states such as Iowa and Illinois; therefore, one would expect a larger elasticity for areas in Kentucky.

The coefficient for the relative price of soybeans was significantly different from zero in five of the fourteen area equations. The cross-price elasticity ranged from −.54 to −1.00 in the short run and from −1.78 to −4.17 in the long run for these five areas.

The coefficient for the variable used to measure the government program for corn, the minimum diversion required to qualify for the price support program in areas 1 through 8 and the maximum allowed under the price support program in areas 9 through 14, was significant at the 5% level for all areas. The short-run elasticity for the government program varied from −.08 to −.26. The coefficient for lagged corn acreage was also significant at the 5% level for all areas. This coefficient varied from .37 to .76, which implies that it takes from 1.6 to 4.2 years for Kentucky farmers to adjust completely to changes in the other independent variables.

Table 2 shows the results of the corn acreage supply function when statewide data is used. Ordinary least squares was used to arrive at these estimates. The aggregated results for corn acreage are rather poor. The own-price coefficient is negative and nonsignificant. This contrasts with the consistently positive sign on the own-price coefficient for the area equations. The sign of the coefficient for the relative price of soybeans in the corn equation has the expected negative sign, but it is not significantly different from zero at the 5% level. The cross-price elasticity in the corn equation is also fairly low, −.21. The coefficient on lagged corn acreage and the government program are both significant and of the expected sign. However, the explanatory power of the statewide model, as measured by R^2, is about as high as the individual area models. This suggests that multicollinearity could be more of a problem in the statewide model.

Covariance analysis was used to test whether the area corn acreage equations could be aggregated. Covariance analysis is used to test whether a model varies between classes (or areas for this study). Given a general specification, covariance analysis

[1] Area prices were available from 1964–79 only. For earlier years these prices were extrapolated by using predicted values from a simple linear regression of respective area prices and the average price for the entire state. This procedure should be reliable because crop prices were relatively stable during the 1960–64 period.

[2] Long-run elasticities were calculated by dividing each elasticity by the adjustment coefficient (derived from the lagged acreage variable).

tests whether the intercepts differ by class (area) and whether the slopes differ by class (area). This analysis was performed on the model specified in equation (1) to test whether the slopes and/or intercepts for the corn acreage supply function vary between areas. The tests for equality of slopes and intercepts were performed by fitting the equations to data with the coefficients constrained to be equal. The results of the constrained regression models are not reported, but are available from the authors upon request.

When acreage equations are constrained such that the slope coefficients are equal (intercepts by area are allowed to differ), the results are similar to the area results. All slope coefficients are of the expected sign and significant at the 1% level. However, the test of the hypothesis that the area slope coefficients are equal is rejected at the 1% level.

Table 2. Corn Acreage Response Functions Using Statewide Data

Dependent Variable		PC_{t-1}	PS_{t-1}	AC_{t-1}	GP_t^a	R^2
AC_t	Coefficient	−414	−5,591	.32*[b]	−1,361**	.82
	standard error	(7,963)	(3,482)	(.14)	(284)	
	mean elasticity	−.01	−.21	.31	−.15	

[a] GP_t is the minimum diversion required to qualify for the price support program for corn.
[b] One asterisk implies significance at the 5% level; two, at the 1% level.

The hypothesis that area intercepts are equal is also rejected at the 1% level.[3]

Summary and Conclusions

This paper continues the trend toward the use of more disaggregated models of acreage supply. The results of this study show that breaking down data to the substate level can improve significantly corn acreage supply analysis. The area equations were far superior to the statewide analysis. Most area equations had the expected signs for the coefficients. This was not true for the statewide results. The result that both slopes and intercepts vary between areas indicates that some aspects of corn acreage supply differ between areas. This difference between areas could be due to different production functions, adjustment parameters, or producer reactions to price changes.

This improvement using substate data is not only obtained by allowing areas to have different intercepts and slopes, but also by using the seemingly unrelated regression model. If some explanatory variable is missing from the specification, the SUR technique may account for some variation in the missing variable; thereby yielding estimates which are more asymptotically efficient.

The results of this study lend support to disaggregated acreage response models for states with diverse agriculture. However, for most major corn-producing states it is possible that such a breakdown would not improve the analysis as much as for Kentucky. Therefore, it is unknown whether such a breakdown would be worth the added cost of data collection and analysis for other states.

[*Received September 1980; revision accepted May 1981.*]

[3] A covariance analysis was also applied to the log-linear models for corn. The hypothesis tested, in this case, is that the elasticities were the same for each area. This hypothesis was rejected at the 1% level.

A Preliminary Evaluation of Price Forecasting Performance by Agricultural Economists

James C. Cornelius, John E. Ikerd, and A. Gene Nelson

The purpose of this note is to review the results of past AAEA-sponsored commodity outlook surveys and to evaluate forecasting accuracy and performance. We discuss the methodology for conducting such a review and suggest some factors that seem to affect the accuracy of responses. How does the span of the forecast affect accuracy? Is it easier to forecast prices for some commodities than others? Are some forecasters more accurate than others?

Background and Survey Procedure

The Survey of Annual Outlook Information is the result of an initiative begun by the AAEA Agricultural Statistics Committee in 1977. A committee task force proposed the survey and an outlook symposium as part of annual AAEA meetings and outlined procedures which have since been followed.

Survey forms are mailed to selected AAEA members in early summer with the request that completed forms be returned two to four weeks before the annual meeting to insure timely information. Various lists of agricultural economists, including regional extension committees, industry outlook groups, USDA outlook staff, and previous survey participants, are used.

No attempt is made to obtain a random sample of the AAEA membership nor to obtain a statistically representative sample of AAEA members involved in outlook work. So, it is not possible to draw conclusions concerning outlook opinions of the AAEA in general from this survey. The primary purpose has been to provide stimulus for discussion of agricultural outlook at the annual meeting.

The survey questionnaire asks for outlook forecasts of production, disappearance, and prices for specified agricultural commodities and indices of agricultural income, land value, and general price levels. Respondents are asked to provide forecasts for only those items about which they feel professionally competent. The outlook forecasts are made for two periods: the current year and the next year. For example, in June of 1978, forecasts were made for 1978 and 1979. This format has led to some misunderstanding by respondents, especially concerning wheat, because the designated crop year does not correspond to the calendar year.

Survey Response

There were fifty-three responses to the survey questionnaire in 1978, including thirty-six university economists, eleven from industry and business, and six from government agencies. Of the fifty-three, twenty indicated that forecasting was a major responsibility in their position. There were seventy-four respondents to the 1979 survey, fifty from universities, thirteen from industry and business, and eleven from government agencies. Twenty-five of these respondents had major forecasting responsibilities.

The AAEA outlook surveys in 1978 and 1979 have been summarized (Ikerd) and briefly reviewed (Futrell) as a first step in evaluating the survey results. A 1980 survey also was undertaken but the results have not yet been evaluated. The following section is a more detailed assessment of the 1978 and 1979 surveys. It is designed to demonstrate methodology for evaluating the outlook survey results and the survey procedure.

Procedure for Analysis

Individual responses were coded to allow for adding new respondents in succeeding years and additional data for past respondents. The consistency of response varied among individuals. Most made point estimates, but others specified a range. When a range was given, the high and low of the range were averaged into a point estimate.

Interpretation of Results

The distributions illustrated in figure 1 present a graphic review of respondents' forecasting performance. Only two representative price forecasts from the survey are illustrated here—slaughter cattle and soybeans. Each forecast is identified by the year of the forecast followed by the year for which the forecast was made. Thus, 78/79 is a forecast made in 1978 for the year 1979. The selection of

Ikerd is a professor, Department of Agricultural Economics, Oklahoma State University; and A. Gene Nelson is a professor, Department of Agricultural and Resource Economics, Oregon State University.

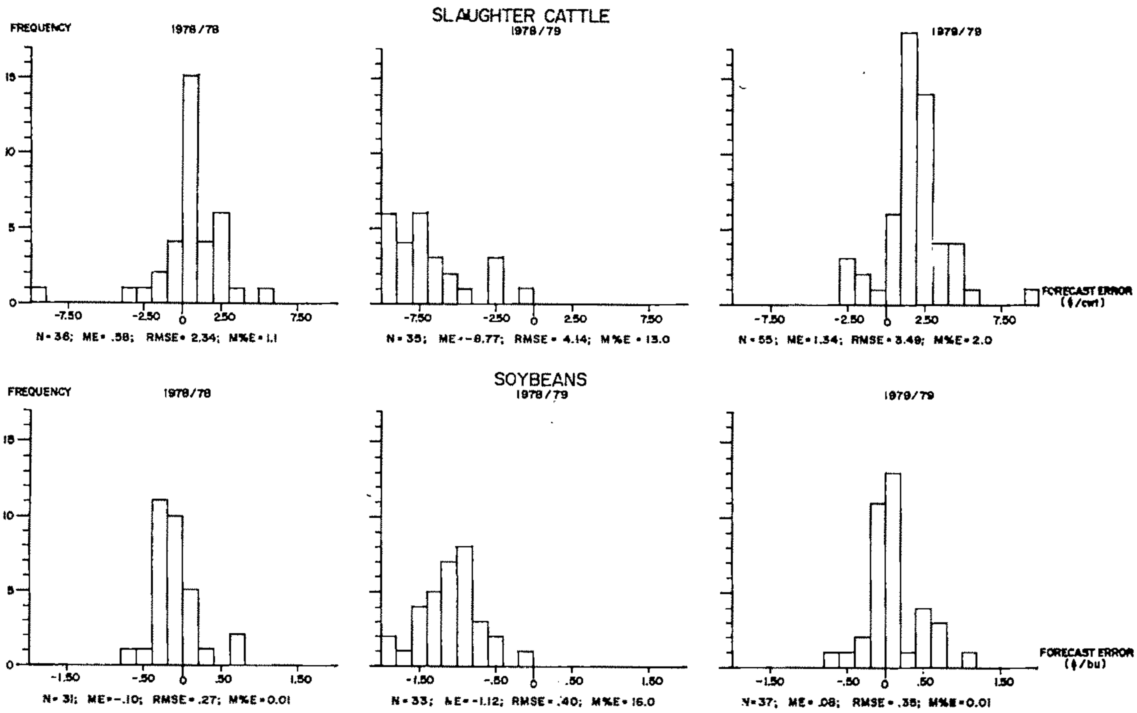

Figure 1. Distribution of price forecast error

distribution intervals for the price prediction error was subjective, based on the observed ranges of the errors.

In addition to the distribution of forecast errors, additional evaluation statistics are listed beneath each graph. These include: *N*, number of respondents; *ME*, mean forecast error; *RMSE*, root mean-squared error; and *M%E*, mean percent error. Intercommodity comparisons for five major commodities including slaughter cattle and soybeans are shown in table 1.

Depending upon one's objectives, it might be appropriate to compute other evaluation statistics if the data base is expanded. These might include tracking measures such as indices of forecast error over and under actual values, error decompositions, and cyclical or dynamic properties of the responses (Dhrymes, P. et al., Mincer and Zarnowitz, Granger).

Preliminary Findings

A few tentative conclusions can be drawn about the three questions. How does the span of the forecast affect accuracy? Is it easier to forecast prices for some commodities than others? Are some forecasters more accurate than others?

The difference in accuracy associated with the span of the forecast can be evaluated by comparing

Table 1. Mean Percentage Price Forecast Error and Root Mean-Squared Error, Selected Agricultural Commodities, AAEA Outlook Survey, 1978 and 1979

		Period					
		1978/78		1978/79		1979/80	
Commodity	Forecast Unit	M%E	RMSE	M%E	RMSE	M%E	RMSE
		(%)	($/unit)	(%)	($/unit)	(%)	($/unit)
Choice Slaughter Steers	$/cwt	1.1	2.34	13.0	4.14	2.0	3.49
Choice Feeder Steers[a]	$/cwt					3.0	5.67
Barrows & Gilts	$/cwt	3.2	2.34	4.7	3.73	0.8	1.68
Corn	$/bu	6.0	.14	12.0	.15	2.0	.09
Soybeans	$/bu	0.01	.27	16.0	.40	0.01	.35

[a] Feeder cattle were not included in the 1978 outlook survey.

the estimates made in 1978 for the 1979 year with the estimates made in 1979 for the 1979 year. For selected commodity price forecasts (cattle, hogs, corn, and soybeans), the 1979 estimates were more efficient measured by either the mean percentage error or the root mean-squared error (table 1). This is to be expected since some monthly price data were already reported for the current year at the time the forecasts were made. There is more information available for short-run, as compared to long-run, forecasts.

A second generalization is that forecast accuracy varies among commodities. For example, for current years, soybean price forecasts have been much more accurate than corn in terms of the mean percentage error (table 1). For the livestock commodities, it appears that hog prices are easier to forecast than cattle prices. However, these data represent a very limited sample. The distribution of random error among the commodities may be unequal, and a longer time series of data would permit more accurate intercommodity forecast error comparisons.

Even with only two years' data, there is the intriguing opportunity to compare the performance of individual forecasters who responded to both surveys. For example, consider the seventeen respondents who forecast current year slaughter cattle price in both 1978 and 1979. Performance statistics can be calculated to evaluate their "track records" of accuracy. Nine of the seventeen forecasters had relatively good track records. The others exhibited a declining degree of accuracy, at least during the two years sampled. The potential for using these results to improve forecasting performance may be limited because the present survey format pledges anonymity of the respondents.

Issues for Further Study

Preliminary comparisons of survey results—among commodities, among forecast spans, and among forecasters—point to some challenging issues in forecasting accuracy. For example:

(*a*) Why can the prices of some commodities be forecast with geater accuracy than others? What can be done to improve the accuracy of these others?

(*b*) For what forecast span (one month, one quarter, one year, two years, etc.) can forecasts be made accurately? Does the length of this span vary with the commodity involved?

(*c*) Why are some forecasters more accurate than others? How can those with poorer performances improve their accuracy?

The limitations inherent in drawing conclusions regarding forecasting performance for a two-year data series must be recognized. However, these results do suggest hypotheses, and indicate the potential for continuing to expand this survey. An expanded data base will allow more thorough evaluations of price-forecasting performance.

Simplified Measurement of Consumer Welfare Change

Dennis C. Cory, Russell L. Gum, William E. Martin, and Ray F. Brokken

Various measures of consumer welfare change have been proposed in the literature, each claiming relative superiority in accurately reflecting the income equivalent of a welfare change. Selection of an appropriate measure in empirical research is complicated by both theoretical and estimation considerations. Compensating variation (CV) and equivalent variation (EV) as measures of consumer welfare change normally are preferred theoretically since they indicate whether or not a policy change is a potential Pareto improvement. However, use of Paasche Variation (PV), Laspeyres Variation (LV), or consumers' surplus (CS) measures is desirable empirically since less information is required for calculation. While Hicks long ago (1943) suggested that the distinctions among these measures would be of little empirical significance in applied studies, other recent authors, including Mishan, have insisted on the necessity for theoretical precision.

Willig established the usefulness of CS as an approximation to CV and EV measures of consumer welfare change under specified conditions. However, conditions under which PV and LV can be useful have not been rigorously developed. In this paper, guidelines are developed for using PV and LV as empirical approximations for theoretically preferable CV and EV measures. These guidelines require less information than those developed by Willig and PV and LV measures have several additional advantages in applied research.

Alternative Measures of Consumer Welfare Change

The relationships among the CV, EV, PV, LV, and CS measures of consumer welfare change are illustrated in figure 1 for a single price decline.

Compensating variation is the amount of compensation, paid or received, that will leave the consumer in the initial welfare position (U_0) following the change in price if any quantity of the commodity can be bought at the new price. Consider a consumer with income Y_0 initially in equilibrium at point A. Income of BB_1 could be forgone while allowing reestablishment of equilibrium at point C with no change in utility. In this example, BB_1 is the compensating variation measure of the consumer welfare change. This value corresponds to the area P_0IFP_1 in price-commodity space bounded by the original and new price lines and the compensated demand curve D_C.

Equivalent variation is the amount of compensation, paid or received, that will leave the consumer in the subsequent welfare position (U_1) in the absence of a price change if any quantity of the commodity can be bought at the old price. For the consumer initially in equilibrium at A, an income increment of AA_1 would be required to achieve the utility level equilibrium at the lower price (point B) should the initial price levels prevail (point D). In this case, AA_1 is the equivalent variation measure of the change in consumer welfare. This value corresponds to the area P_0GKP_1 bounded by the price lines and the compensated demand curve D_E.[1]

The consumer's surplus change in this example is given by P_0IKP_1, the area bounded by the price lines and the ordinary Marshallian demand curve D_m. Comparing these measures for the case of a single price decline yields the familiar relationship, $CV < CS < EV$. The inequalities reverse for a price increase.

Laspeyres variation is the exact change in income required to allow the purchase of the original quantities of all goods after prices have changed. Paasche variation, on the other hand, is the exact change in income required to allow the purchase of the subsequent set of goods when facing the initial price situation. For the case of a single price fall in figure 1, LV would equal AA_2 while PV would equal BB_2, bounding the CV, CS, and EV measures of consumer welfare change. In price-commodity space, LV is given by P_0IHP_1, and PV is given by P_0JKP_1. Comparing all five measures of consumer welfare change for a price decline illustrates that

Arizona Agricultural Experiment Station Journal Article No. 3425.

The authors wish to thank Andrew Schmitz and Darrell Hueth for helpful comments on an earlier draft.

[1] Some analysts feel that a more operational definition for compensating variation is "the amount of income which must be taken away from a consumer (possibly negative) after a price and/or income change to restore him to his original welfare level." This definition results in a measure that is positive for a price fall and negative for a price rise. If one is interested in performing compensation tests and adding up gains and losses over various groups, it is essential that compensating variation for price rise have a different sign from the compensating variation for a price fall. An analogous definition is made for equivalent variation.

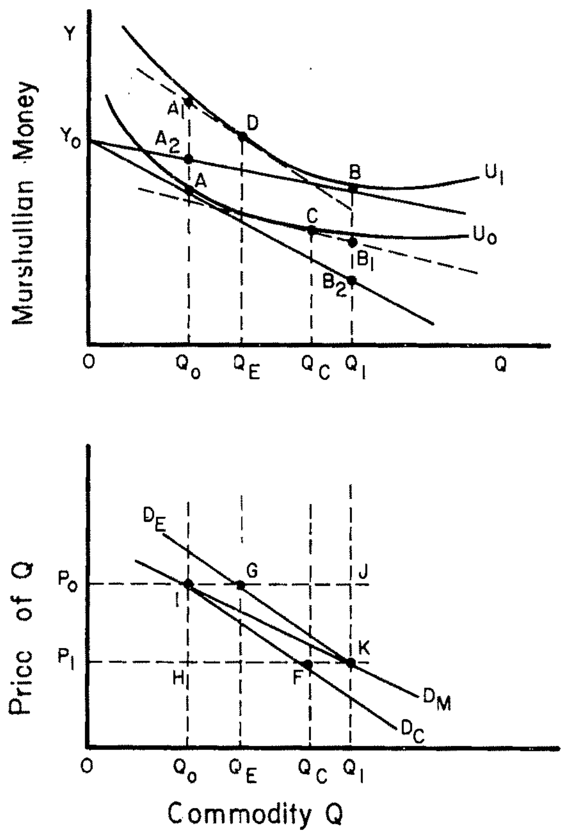

Figure 1. Compensating, equivalent, Paasche, and Laspeyres variations for the case of a price decline

$LV < CV < CS < EV < PV$. That is, LV and PV bound CV, CS, and EV. On the other hand, LV and CS bound CV, and PV and CS bound EV. All inequalities reverse in the case of a price increase.[2]

The desirability of using CV or EV as a measure of consumer welfare change is well established in the theoretical literature whenever post-policy quantity adjustments are possible. Yet, CS, LV, and PV can be easily calculated in empirical studies. In the following section alternative approximations for CV and EV using CS, LV, and PV are discussed.

Approximations for Compensating and Equivalent Variation Measures

Willig established the validity of the following rules of thumb for a single price change; if $|\bar{\eta}A/2m^o| \le .05$, $|\underline{\eta}A/2m^o| \le .05$, and if $|A/m^o| \le .9$, then

$$(1) \qquad \frac{\underline{\eta}|A|}{2m^o} \le \frac{CV-A}{|A|} \le \frac{\underline{\eta}|A|}{2m^o}, \text{ and}$$

$$(2) \qquad \frac{\underline{\eta}|A|}{2m^o} \le \frac{A-EV}{|A|} \le \frac{\bar{\eta}|A|}{2m^o},$$

where A is consumer's surplus area under the demand curve and between the two prices, CV is compensating variation corresponding to the price change, EV is equivalent variation corresponding to the price change, m^o is consumer's base income, and $\bar{\eta}$ and $\underline{\eta}$ are, respectively, the largest and smallest values of the income elasticity of demand in the region under consideration. Notice that while these formulas place observable bounds on the percentage errors made by approximating CV or EV with the observable CS, consumer income and income elasticity data are required to make the rules operational.

Using the bounding properties of PV and LV, additional rules of thumb can be derived which (a) place observable bounds on the percentage error of approximating CV with either CS or LV (b) place observable bounds on the percentage error of approximating EV with either CS or PV, (c) require no information about consumer income or income elasticities, and (d) establish conditions under which the easily understood PV and LV measures of welfare change can be reported to policy makers.

Assuming that the demand curve is linear over the range under consideration, it follows that

$$(3) \quad \frac{CS-LV}{|CS|} \le \lambda \text{ when } |\Delta Q| \le \frac{2\lambda}{(1-\lambda)} Q_o, \text{ and}$$

$$(4) \quad \frac{PV-CS}{CS} \le \lambda \text{ when } |\Delta Q| \le \frac{2\lambda}{(1-\lambda)} Q_o,$$

where CS, LV, PV are defined as before, λ is a specified percentage of error, ΔQ is change in quantity demanded resulting from the price change, and Q_o is original quantity demanded. Refer to figure 1. Equation (3) is derived as follows. As the price falls from P_o to P_1, the consumer is assumed to move along the linear Marshallian demand curve D_M, increasing quantity demanded from Q_o to Q_1. Let $\alpha = P_oIHP_1$ and $\beta = IHK$, then $\frac{CS-LV}{|CS|} = \frac{\beta}{\alpha+\beta}$. Thus, $\frac{CS-LV}{|CS|} \le \lambda$ implies that $\frac{\beta}{\alpha+\beta} \le \lambda$ so that $\beta \le [\lambda/(1-\lambda)]\alpha$. This expression can be rewritten as $\frac{1}{2}\Delta P \cdot \Delta Q \le [\lambda/(1-\lambda)]\Delta P \cdot Q_o$ from which it follows that $\Delta Q \le [2\lambda/(1-\lambda)]Q_o$. The derivation is similar for (4).

An example can illustrate the usefulness of (3) and (4). If a value of .05 is selected for λ, then LV and PV will be within 5% of CS whenever the change in quantity demanded is less than 10% of the original quantity demanded. Since LV and CS bound CV (and PV and CS bound EV) for a single price decline, it follows that whenever $\Delta Q \le 10Q_o$, CS and LV are within 5% of CV. Moreover, CS and PV are within 5% of EV. That is, LV and PV can be used unapologetically for CV and EV, respectively,

[2] Paasche and Laspeyres variations were discussed by Hicks in 1942. These measures acquired their names by analogy to Paasche and Laspeyres indexes, but are, in fact, much simpler computations. For a discussion of the development of CV, EV and CS, see Currie, Murphy, and Schmitz.

in all cases where quantity demanded changes by less than 10% of the original quantity demanded.[3]

In general, knowing the quantity change which results from a price change, use of (3) and (4) allows an easily calculated upper bound on the associated percentage error which might result from using PV, LV or CS approximations to CV and EV. Moreover, this calculation only requires price and quantity change information and not income and income elasticity information as required by Willig's formulas shown in (1) and (2). Finally, for policy makers willing to accept a percentage estimation error of λ, these rules provide criteria against which the acceptability of PV and LV approximations of CV and EV can be evaluated. PV and LV are particularly useful approximations when the associated estimation error is acceptable, since both measures have clear intuitive interpretations, overcoming objections of Cochrane and others who argue that CV, EV, and CS measures of consumer welfare change are incomprehensible to policy makers.

Implications for Applied Research

These results suggest a pragmatic approach to applied policy analysis. First, the Paasche and Laspeyres measures of welfare change should be calculated. This quick and inexpensive computation provides a range in which the actual value of the consumer welfare change will lie. Next, assuming a direct linear path of price-quantity adjustment, the midpoint of this range is the estimate for the change in CS. In many policy contexts, this simple two-step procedure will provide adequate information for rigorous decision making.[4]

In short, PV and LV measures of consumer welfare change provide policy analysts with a simple, useful, and theoretically coherent evaluation tool. Careful utilization of these analytic tools in applied benefit-cost studies could be productively employed much more frequently.

[3] It is rare that a quantity change of as much as 10% would be the expected result of a proposed policy. For example, all lands ever developed for irrigation as federal reclamation projects are only 2.5% of total U.S. cropland (Martin). Pimental and Shoemaker estimate that a complete ban on insecticides in the production of corn would result in only a 3% reduction in U.S. corn yield.

[4] For an application of this simple method in an agricultural policy context, see Cory, Gum, Martin, and Leigh.

Optimal Choices among Alternative Technologies with Stochastic Yield

Joseph Yassour, David Zilberman, and Gordon C. Rausser

Often, farmers have to choose among discrete alternatives with uncertain outcomes. This occurs, for example, when farmers consider adoption of new technologies, such as new farm machinery or irrigation systems. Understanding the process of technological adoption requires the explicit recognition of uncertainty and risk aversion. The purpose of this paper is to advance a new approach for investigating this process. It will be demonstrated that this approach is, in many respects, superior to current approaches.

Current Approaches

Expected utility is the major approach employed in analyzing farmers' behavior under uncertainty. Since its introduction by von Neumann and Morgenstern, it has been refined and extended to explain the behavior of economic agents. Sandmo has introduced a general model which requires neither the specification of the utility function nor the distribution of the random variable. It assumes multiplicative risk and is limited to problems with only one random variable. Sandmo's model has been modified by Feder to analyze the adoption of new technologies in less developed countries. While these theoretical models are interesting and insightful, their empirical weakness lies in their theoretical strength. They are too general. Quantitative analysis requires more detailed specifications.

Another method of risk analysis consistent with expected utility is stochastic dominance (Anderson). While these rules have the advantage of not requiring knowledge of utility functions, their practical use is restricted to comparison of discrete alternatives; and they are often inconclusive.

When the distribution of the random variable is described by only two parameters or the utility function is quadratic, Tobin has demonstrated that the expected utility can be introduced as a function of the mean and the variance. The behavior of farmers under uncertainty is studied frequently using the mean-variance (E-V) analysis assuming that farmers maximize a linear combination of the mean and the variance (Freund, Pope and Just). This corresponds to maximization of expected utility of income when either the utility function is quadratic or the random variable is normally distributed and the measure of absolute risk aversion is constant. These assumptions are quite restrictive. Quadratic utility is unacceptable for theoretical reasons because it implies increasing absolute risk aversion (Arrow, Pratt). On the other hand, many natural phenomena are described by probability distributions that are not normal. For example, Day has shown that crop yields can be best represented by the Gamma distribution. Moreover, the Gamma distribution was found to be accurate in representing precipitation and drought occurrence (Starr, Rudman, Whipple). Thus, the use of the convenient linear E-V framework in these cases corresponds to the imposition of a quadratic utility function with all of its associated limitations.

New Approach

A new framework, which is equally convenient and includes as a special case the linear mean-variance analysis, will be referred to as the exponential utility, moment-generating function approach (EUMGF). This approach assumes an exponential utility function which implies constant absolute risk aversion rather than increasing absolute risk aversion (Arrow, Pratt). This utility function can be applied conveniently in conjunction with all distributions which have moment-generating functions. Moreoever, under certain criteria, technology choices made by the EUMGF approach are applicable for decision makers with decreasing absolute risk aversion.

The Model

Suppose a farmer must decide whether to continue employing his existing technology, T_0, or to adopt a new technology, T_1. Each technology is presumed to have deterministic variable costs of c_0 and c_1 and stochastic yields, Y_0 and Y_1, respectively. The net profit under technology, i, is the random variable, R_i,

Giannini Foundation Paper No. 627.

$$R_i = PY_i - c_i, \tag{1}$$

where $i = 0, 1$, and P is the fixed output price.

Given the above specifications, the new technology will be adopted if

$$E_1\, U(R_i) > E_0\, U(R_0), \tag{2}$$

where U is the utility function and E_i is the expectation operator for the yield distribution of the ith technology. The EUMGF approach assumes exponential utility function, i.e.,

$$U(R) = -e^{-rR}, \tag{3}$$

where r is the measure of absolute risk aversion. Substituting equations (3) and (1) into equation (2) provides the basis for introducing the moment-generating function and, thus, obtains a compact analytical solution. That is,

$$E_1\, [-e^{-r(Y_1P-c_1)}] > E_0\, [-e^{-r(Y_0P-c_0)}]\ , \tag{4}$$

which is equivalent to

$$e^{rc_1}\, M_1(-rP) < e^{rc_0}\, M_0(-rP), \tag{5}$$

where

$$M(t) = E\, e^{tY} \tag{6}$$

is the moment-generating function of the yield-probability distribution.

The Case of Normal Yield Distributions

When the distribution of yields under both technologies is normal, the EUMGF reduces to the linear E-V framework. The moment-generating function of the normal distribution is

$$M(t) = \exp\left(\mu t + \sigma^2 \frac{t^2}{2}\right), \tag{7}$$

where μ and σ are the mean and standard deviation. Substituting equation (7) into equation (5), taking natural logarithm and simplifying the outcome, we have

$$P[(\mu_1 - \mu_0) - (c_1 - c_0)] - \left[\frac{r}{2} P^2(\sigma_1^2 - \sigma_0^2)\right] > 0. \tag{8}$$

As equation (8) suggests, the new technology will be adopted if the increase in the expected profit exceeds the increase in the variance times half the risk-aversion measure. This condition is obtained also when the objective is to maximize the expected profit less $r/2$ times the variance, i.e., $E - (r/2)\ V$.

Since expected profit is measured in monetary terms, the above results indicate that for the EUMGF approach,

$$CE_n(T_i) = P\mu_i - \frac{r}{2} P^2\sigma_i \tag{9}$$

is the certainty equivalent of profit under the ith technology when the yield is normally distributed. The risk premium is $(r/2)P^2\sigma_i^2$, where $r/2$ is the price per dollar of variance (r is also the measure of constant absolute risk aversion, i.e., $r = -U''/U'$). Condition (8) ensures that the technology with the higher certainty equivalent is chosen.

The Case of Gamma Yield Distributions

As indicated above, there is sufficient evidence to indicate that yields are better approximated by skewed distributions such as gamma. The density function for the gamma distribution is

$$f(Y) = \frac{\lambda^\alpha}{\Gamma(\alpha)}\, Y^{\alpha-1}\, e^{-\lambda Y}, \tag{10}$$

where $Y > 0, \Gamma(\alpha)$ is the complete gamma function, and α and λ are the parameters of the distribution. The moment-generating function of the gamma distribution is

$$M(t) = \frac{1}{(1 - t/\lambda)^\alpha}. \tag{11}$$

Substituting equation (11) into equation (5) and taking the logarithms of both sides yields a condition (stated in monetary units) for the adoption of the new technology,

$$\frac{\alpha_1 \ln(1 + rP/\lambda_1)}{r} - c_1 > \frac{\alpha_0 \ln(1 + rP/\lambda_0)}{r} - c_0. \tag{12}$$

The expressions on both sides of equation (12) are the certainty equivalents of profits under a specific technology. Since the mean of gamma distribution is α/λ and the variance is α/λ^2, the certainty equivalent of the ith technology for the gamma distribution can be derived from equation (12), i.e.,

$$CE_Y\,(T_i) = \frac{1}{r}\left(\frac{\sigma_i}{\mu_i}\right)^2\ \ln\left(1 + \frac{\sigma_i^2}{\mu_i} rP\right) - c_i; \tag{13}$$

and the condition for adoption of the new technologies can be expressed in terms of the respective mean and variance of yields, i.e.,

$$\frac{1}{r}\cdot\left(\frac{\mu_1}{\sigma_1}\right)^2 \ln\left(1 + \frac{\sigma_1^2}{\mu_1} rP\right) - c_1 > \frac{1}{r}\left(\frac{\mu_0}{\sigma_0}\right)^2 \ln\left(1 + \frac{\sigma_0^2}{\mu_0} rP\right) - c_0. \tag{14}$$

Special Cases of Gamma Yield Distributions

The decision rule for the choice of technology becomes much simpler for two special cases of the gamma distribution, namely, the chi-squared and

exponential distributions. When the parameters of the gamma distribution are $\alpha = N/2$ and $\lambda = 1/2$, the distribution becomes chi-squared with N degrees of freedom. Introducing these results into equation (12) and noting that the mean of a chi-squared distribution is its degrees of freedom ($N = \mu$), the rule for selecting the modern technology when both technologies have a chi-squared yield distribution is

$$(15) \qquad \mu_1 - \mu_0 > 2r \frac{(c_1 - c_0)}{\ln (1 + 2rP)}.$$

When the mean of a gamma distribution is equal to its standard error, the distribution becomes exponential. Introducing $\mu_i = \sigma_i$ into equation (14) and rearranging the terms, the rule for the selection of the modern technology when the yields are exponentially distributed is

$$(16) \qquad \ln \frac{1 + r\mu_1 P}{1 + r\mu_0 P} > c_1 - c_0.$$

Comparison of Normal and Gamma Yield Distributions

To understand how different specifications of the yield distribution affect the choice of technology, consider two yields with the same mean and variance but with different distribution. Using a Taylor expansion of the logarithmic function and assuming $(\sigma^2/\mu)rP < 1$, the CE of the gamma distribution in equation (13) becomes

$$(17) \quad CE_\gamma(T) = \frac{1}{r}\left(\frac{\mu}{\sigma}\right)^2 \sum_{j=1}^{\infty} (-1)^{j-1} \frac{1}{j}\left(\frac{\sigma^2}{\mu} rP\right)^j - c,$$

where j is the index.

Subtracting equation (9) from equation (17) yields the difference between the CEs of the gamma and normal distributions:

$$(18) \quad CE_\gamma(T) - CE_n(T) = \frac{1}{r}\left(\frac{\mu}{\sigma}\right)^2 \sum_{j=3}^{\infty} (-1)^{j-1} \frac{1}{j}\left(\frac{\sigma^2}{\mu} rP\right)^j.$$

Assuming that all elements from $j = 4$ on are insignificant, expression (18) reduces to

$$(19) \quad CE_\gamma(T) - CE_n(T) \approx \frac{1}{3} \frac{\sigma^4 r^2 p^3}{\mu} > 0.$$

It is clear from equation (19) that a random yield with gamma distribution is preferred to that with normal distribution if both have the same mean and variance and equal production cost. This result clarifies the limitations of the frequently assumed normal distribution for decision-making purposes in cases where the actual distribution is skewed. As shown in equation (19), this misspecification leads to underestimation of the benefit from the random yield and may also result in erroneous decision making. In particular, if a linear E-V framework is employed assuming incorrectly that yields are normally distributed when, in fact, they are gamma distributed, the resulting choices are generally too conservative.

The importance of the above result will be illustrated by a simple example and by an empirical example. For the simple illustration, suppose the existing technology has mean, μ, and standard deviation, σ; and a new technology is introduced with the same production cost and a random yield which is an indefinite number, k, times the existing technology yield. Using equations (9) and (13), the CEs of the new technology under both the normal and gamma distributions are

$$(20) \quad CE_n\,(T_k) = k\left(P\mu - \frac{k}{2} rP^2\,\sigma^2\right) - c,$$

$$(21) \quad CE_\gamma\,(T_k) = \frac{1}{r}\left(\frac{\mu}{\sigma}\right)^2 \ln\left(1 + \frac{k\sigma^2}{\mu} rP\right) - c.$$

These two CEs are depicted as functions of k, the technology multiplier, in figure 1.

The CE for the gamma distribution is always higher than that of the normal distribution and increases at a decreasing rate with k. The CE for the normal distribution rises for relatively small k's, peaks at $k = \mu/\sigma^2 rP$, and decreases thereafter. Thus, technologies with higher multipliers are always preferred under the gamma distribution. However, they will not be preferred if the yield distribution is assumed to be normal. In figure 1, for example, T_1 is inferior to T_{k_1} for the gamma distribution but is superior for the normal distribution.

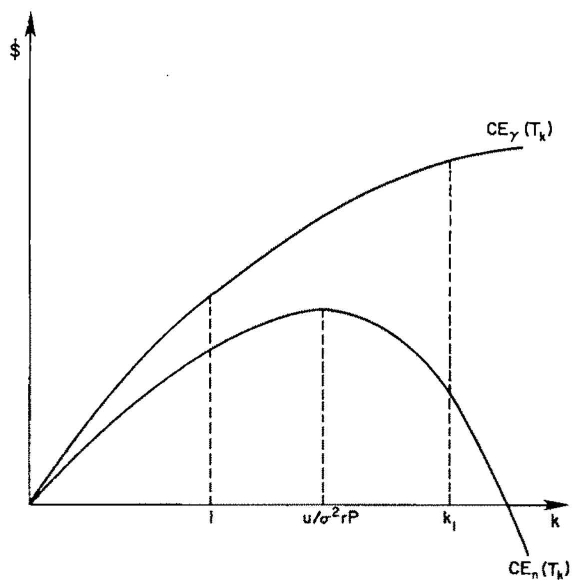

Figure 1. Certainty equivalents under gamma and normal yield distributions

The importance of using the right specification increases with the measure of risk aversion. From equations (9) and (13) it can be derived that both *CE*s decrease with r, but the *CE* under the normality assumption decreases more rapidly. Thus, the difference between the two *CE*s increases with the degree of risk aversion. The above results have another implication—assuming a normal distribution of yield will result in underestimation of the Arrow-Pratt measure of risk aversion if, in fact, the real distribution is skewed.

Turning to the empirical example, we employ data reported by Roumasset concerning production technologies available to operators of the rice land in the Philippines. Four technologies are considered. One is a traditional technology, denoted by T_0, which is lowest in yield as well as lowest in cost and risk. The other three, denoted by T_1, T_2, and T_3, are modern technologies. They use high-yield variety seeds combined with cash inputs (such as fertilizer) and require more labor. Among them, T_1 has the lowest costs and yields, while T_3 has the highest yield and also the highest cost. The means and standard deviations of the yield for the four technologies, as well as output price and production cost per acre, are given in parentheses in table 1. The table presents the certainty equivalents of profits under the four technologies for a farm with 1 hectare of land. These certainty equivalents are computed for the two yield distribution specifications (i.e., normal and gamma) under different degrees of risk aversion. The measure of absolute risk aversion varies from zero (risk neutrality) to .01. The optimal choices under both distribution specifications for each level of risk aversion are given in separate columns.

Under both specifications, increases in risk aversion result in a gradual move to less risky technologies. This tendency is much stronger under normality. For example, for the gamma distributions, all the farms with $r \leq .003$ will adopt the most modern techniques, while only the farms with $r \leq .001$ will do so under normality. The traditional technology will be adopted by all the farms with $r \geq .005$ under normality but only by the farms with $r \geq .009$ under gamma distribution. The effect of an increase in risk aversion on the certainty equivalents is much more drastic under the normal distribution, especially for the high-risk technology. Note that the certainty equivalent of the most modern technology is negative and rapidly declines for $r \geq .007$.

Other Yield Distributions

The gamma and normal yield distributions are simply illustrative of the analysis that can be conducted using the methodology developed here. Any continuous or discrete yield distribution with a well-behaved, moment-generating function can be analyzed. Moreover, in many cases, a new technology results in stochastic yield which differs from that of the existing technology not only in the parameters but in the type of the distribution. Consider, for example, a case where the yield under the existing technology, T_0, has a continuous distribution, say, chi-squared with N_0 degrees of freedom. Under the new technology, T_1, suppose the distribution of the yield can be best approximated by a Poisson distribution with parameter λ_1. The moment-generating function of the Poisson distribution is given by

$$M(t) = \exp[\lambda(e^t - 1)]. \tag{22}$$

[a] Each technology is defined by μ_i, σ_i, c_i, and **P**.

Following the same procedure as above and using equations (15) and (22), it is found that the new technology is adopted if

$$\mu_1 (1 - e^{-rP}) - \mu_0 \frac{1}{2} \ln (1 + 2rP) > r(c_1 - c_0), \tag{23}$$

where $\mu_0 = \lambda'_0$ and $\mu_1 = \lambda_1$ are the expected yields for the two distributions.

Stochastic Dominance, Decreasing Absolute Risk Aversion, and the Exponential Utility, Moment-Generating Function Approach

First-order stochastic dominance (FSD) and second-order stochastic dominance (SSD) are useful approaches that can be employed for discrete technological choices. Hammond proved that, if the new technology is superior according to the FSD criterion, it will be selected by any risk-neutral or risk-averse firm. If the new technology is superior according to the SSD criterion, it will be selected by strictly risk-averse decision makers. Thus, whenever the new technology is superior according to either the FSD or SSD criterion, it will be selected according to the EUMGF which reflects strict risk-aversion behavior. The main weakness of the stochastic-dominance approach is that it may lead to inconclusive results for many choice situations. By contrast, the EUMGF approach leads to a complete ordering of uncertain profit distributions. For example, the FSD and SSD rules are inconclusive in comparing technologies with normal and gamma profit distributions and the same means and variances (Hammond). The EUMGF approach will select the gamma technology (as equation [19] indicates).

One possible criticism of the EUMGF approach is that it assumes constant absolute risk aversion and, thus, does not admit decreasing absolute risk aversion (DARA). Nevertheless, technology choices made with the EUMGF approach can be used by decision makers with DARA. In comparing modern with old technologies, we expect the modern technologies (i.e., high-yield varieties or chemical fertilizers) to have higher expected profit but less concentrated distributions than the traditional technologies would have. The probability of earning very low or very high profits with the modern technology is higher than with the old technology. Thus, it is plausible that the cumulative yield distribution of profits under the modern technology crosses that of the old technology once from above. For these properties, Hammond found that, if the modern technology is adopted under an exponential utility function, it will also be adopted under utility functions which exhibit DARA as long as the degree of risk aversion for the DARA function is smaller than the absolute risk aversion (say, r) of the former. Similarly, if the old technology is chosen under constant absolute risk aversion, it will also be adopted under DARA when the measure of risk aversion for DARA is always greater than r.

Conclusions

The use of the mean-variance approach to analyze farmers' behavior under uncertainty is often objectionable on theoretical and empirical grounds. Nevertheless, it is commonly applied because of its computability. Therefore, it is desirable to develop alternative methods for risk analysis which are both theoretically sound and easily applied.

One possible direction of research is to assume specific utility functions which are preferred to the quadratic utility function and to use existing results in mathematics and statistics to derive simple expressions for the expected utility of income under various distributions. Such an approach is introduced in this paper and is applied to discrete choices among alternative technologies with random yields. The utility of income was described by the negative exponential utility function. This allows expected utility to be expressed using the moment-generating yield function. The methodology was used to derive specific decision rules for cases where yields are gamma distributed. It showed that the E-V approach may lead to significantly inferior decisions. In general, the use of the decision rule suggested here results in the adoption of a more risky technology in some cases when the mean-variance approach erroneously recommends against its use.

The approach here is applicable to more general situations. For example, the analysis under uncertainty when both price and yield are uncertain allows analysis when total revenue distribution is not normal, even though price and yield are hypothesized to be normal. Also, the approach could easily be extended to accommodate linear combinations of random variables—e.g., revenue and cost uncertainty.

The utility function assumed here implies constant absolute risk aversion. This assumption is more reasonable than is the increasing absolute risk aversion implied by quadratic utility (and the E-V approach). However, Arrow has argued that most individuals have decreasing absolute risk aversion. Thus, even though the new method introduced here is an improvement over the mean-variance approach, economists should continue to seek utility functions with both decreasing absolute risk aversion and simple expressions for expected utility.

Multiple Optimal Solutions in Linear Programming Models

Quirino Paris

Since 1950, empirical studies using linear programs (LP) have all neglected the consequences of one important aspect of mathematical programming. Simply stated, the polyhedral nature of the solution set in LP models may cause multiple optimal solutions if some plausible conditions are realized. If and when empirical problems possess alternate optimal solutions, why is only one of them usually selected for presentation in final reports which, often, also make efficiency judgments and prescribe sweeping policy changes?

When LP is used for analyzing empirical problems, an implicit comparison is usually made between the activities actually chosen and operated by the economic agent under scrutiny and the optimal activities suggested by the model's solution. In several instances (Wicks), the use of LP for policy planning has inspired the use of Theil's U-inequality coefficient to assess formally the discrepancy between actual and optimal (predicted) activities. Desired values of the U coefficient are those close to zero, attained when the squared distance between actual and LP optimally predicted activities is small. Implicitly, however, minimum distance criteria have been used by many authors to assess the plausibility and performance of their LP models. In the presence of multiple optimal solutions, however, the selection of a specific solution for final analysis is crucial and should not be left to computer codes as probably has been the case in all reported studies.

Furthermore, the empirical LP problem is made even more complex by the existence of quasi-optimal solutions; that is, those solutions which change the optimal value of the objective function only by a fractional percentage. Because the information used to specify empirical problems is seldom exact, quasi-optimal solutions may legitimately be considered as suitable candidates for final reporting.[1]

Quirino Paris is a professor of agricultural economics at the University of California-Davis.

Giannini Foundation Paper No. 623.

The author is indebted to R. A. Collins and W. Candler for their helpful comments.

[1] In a brief note, McCarl has suggested perturbation procedures and an ad hoc series of actions to avoid multiple optimal solutions. If perturbation can be used to eliminate multiple optimal solutions, however, it also can be used to generate them (as in the case of almost multiple optimal solutions). Contrary to McCarl's approach, we suggest that the existence of multiple optimal solutions renders the problem richer in information and more interesting to deal with.

The conditions under which multiple primal and dual optimal solutions can occur in linear programming problems are related to the phenomenon of degeneracy, a rather plausible situation in empirical studies. Degeneracy of the primal solution occurs when a set of activities employs inputs in exactly that proportion which exhausts completely two or more available resources. Analogously, degeneracy of the dual solution is encountered when, given an optimal plan, the accounting loss for some nonbasic activity happens to be the same (zero) as that of the activities included in the optimal plan. Hence, the likelihood of either primal or dual degeneracy increases rapidly with the size of the model. Baumol (p. 315) asserts that "computational experience indicates that such cases (primal and dual degeneracy) are encountered more frequently than might be expected in advance." Thus, a correct and informative report of empirical results generated by LP should include complete information about the problem's size and an explicit statement of whether the primal and dual solutions presented are indeed unique.

Unfortunately, a search of the empirical literature has revealed that a majority of papers fail to disclose even the number of columns and rows in the matrix of constraints. No paper mentioned whether or not the reported solutions are unique.

Dealing with Multiple Optimal Solutions

Given the substantial effort and amount of data usually involved in the specification of large LP models, multiple optimal and quasi-optimal solutions should not be regarded as a curse. They are merely processed information incorporated in the model from the start for thoughtful researchers to be aware of. The curious reader, on the other hand, should know about them to appreciate fully the model's capabilities. Reporting of all optimal and quasi-optimal solutions, therefore, does not seem a priori an excessive burden. The informational content of such a reporting easily may outweigh the initial cost of assembling the model.

Two seemingly unrelated ideas provide a plausible criterion to help the researcher in choosing among various optimal solutions. The first is that a convex combination of optimal solutions is itself an optimal solution. This idea can provide an unexplored flexibility for the application of LP meth-

ods to empirical problems. As is well known, the number of positive activity levels included in an extreme point optimal solution cannot exceed the number of constraints. But this restriction is not applicable to convex combinations of extreme point solutions. Hence, the possibility of more diversified optimal solutions should not be ignored.

The second idea is that researchers have often judged their LP models by comparing their performances (in terms of an optimal solution) with actual behavior of the economic agent under study. In the presence of dual degeneracy, this criterion implies choosing the convex combination of optimal solutions in closest proximity to actual activities.

To combine these two ideas, a familiar minimum distance criterion based on minimizing a quadratic loss function, can be used.

Consider the LP problem of choosing a vector $\mathbf{x}$ to

(1) maximize $c'\mathbf{x}$ subject to $\mathbf{A}\mathbf{x} \leq b$, $\mathbf{x} \geq 0$,

where $\mathbf{A}$ is an mxn matrix of known coefficients and the other elements of the problem are conformable to it.

Suppose problem (1) represents a regional production location problem and possesses k alternate primal optimal solutions, $k<n$. Let $\mathbf{P}$ be the matrix whose column vectors are such k-extreme point optimal solutions. Let $\mathbf{x}_a$ be a vector of activity levels actually operated in the region. Then, the problem of choosing a vector $\mathbf{w}$ to

(2) minimize $(\mathbf{x}_a - \mathbf{P}\mathbf{w})' (\mathbf{x}_a - \mathbf{P}\mathbf{w})$ subject to $\mathbf{s}'\mathbf{w} = 1$, $\mathbf{w} \geqslant 0$,

defines a procedure to estimate the weights, $\mathbf{w}$, for the convex combination, $\mathbf{P}\mathbf{w}$, of the k-extreme point optimal solutions. The components of the vector $\mathbf{s}$ are all unitary. The optimality criterion is the least-squares problem of choosing that optimal LP solution, $\mathbf{P}\hat{\mathbf{w}}$, which is closest to the activity levels actually operated in the region.

The formulation of problem (2) is appealing for several reasons. First, the objective function can be viewed as a measure of the loss incurred by the region for not producing according to optimal activity levels that require minimum deviations from present practices. Second, the matrix $\mathbf{P}$ is of full column rank since the optimal solutions that define it are associated with extreme points and are, therefore, independent of each other. Hence, the solution vector of weights, $\hat{\mathbf{w}}$, is unique and, in turn, the projection $\mathbf{P}\hat{\mathbf{w}}$ constitutes an optimal LP solution which itself is unique in the sense defined by problem (2). The components of the $\mathbf{w}$ vector are scalars without unit of measurement because they represent weights of a convex combination. Therefore, changes in the measurement units of the LP activities considered in the model do not affect the estimates of $\mathbf{w}$. In fact, the components of every column in the $\mathbf{P}$ matrix represent the same activities as in the $\mathbf{x}_a$ vector. If measurement units are changed for some activity in the model, they are changed in both the $\mathbf{P}$ matrix and the vector $\mathbf{x}_a$, offsetting each other. Third, if the vector $\mathbf{x}_a$ is a random sample of activity levels—as is usually the case with econometric studies—it is possible to apply the standard statistical procedures to verify hypotheses of how closely the LP model explains the behavior of economic agents.[2] Therefore, when there are multiple optimal solutions, finding a plausible optimal solution of LP problems generally involves a two-stage optimization process. In the first stage, all extreme point optimal solutions are generated. In the second stage, optimal weights are computed to collapse them into an optimal (least distance) convex combination.

The two-stage optimization procedure outlined above is a novel blend of mathematical programming and inferential, statistical technique. In mathematical programming, the researcher assumes knowledge of the problem's structure and asks: What is the optimal response associated with it? In statistical inference, one starts with "real world" observations and asks: What is the most likely structure which generated such observations?

This sharp dichotomy is useful only as a classification scheme. In reality, each approach shares some distinctive features of the other. Thus, on one hand, linear programming models are specified using real world observations in their constraints, input-output coefficients, and revenue vector. Econometric models, on the other hand, assume some elements of the structure of the problem that will constitute the maintained hypothesis. The additional link between mathematical programming and econometrics is represented by the vector of realized activity levels, $\mathbf{x}_a$, which allows a test of the null hypothesis whether or not the linear programming structure is suitable for the problem under investigation.

Approaching the problem of multiple solutions by computing an optimal convex combination, indicated in problem (2), has the advantage of making the most use of all the information contained in the original LP specification. This does not imply that the best-fit solution is preferred to others. But, if a planned optimal solution is implemented by an economic agent, the solution which requires minimal adjustments from present practices ought to be carefully considered.

Validation of LP Models

A survey of the empirical literature reveals that validating LP models vis-à-vis the economic reality they intended to reflect was not often an explicit and formal objective. This is in sharp contrast with econometric and simulation studies in which the

[2] In econometric studies, the observations of realized activity levels, $\mathbf{x}_a$, are assumed to constitute a random sample suitable for hypothesis testing. The character of the $\mathbf{x}_a$ vector does not change when used in the context presented here.

validation process is widely recognized as an essential part of the analysis.

The multiple optimal solution problem clearly shows the necessity of including formal model validation within the LP analysis. To develop a more complete and satisfactory procedure, it seems logical to parallel the inferential methodology of econometrics. Despite their apparent differences, there is a strong analogy between the logical structure of econometric and mathematical programming studies.

In econometric studies, the structural model is always the result of an implicit optimization process assumed to underlie the behavior of economic agents. That is, economic agents are assumed to maximize utility, profit, or expected utility. In linear programming, such an optimization process is always explicit and corresponds to the LP model itself. The LP constraints can be regarded as structural form relations.

In econometrics, the inferential process and validation methodology rely upon two fundamental steps: identification and hypothesis testing. Linear programming analysis, especially when multiple optimal solutions occur, faces the same twofold process. To be sure, the large size of most empirical models tends to reduce the importance of the identification problem. Formally, such a problem can be stated as follows: given the LP structural form relations $Ax \leq b$, is it possible to find a matrix $\mathbf{T}$ such that the system $\mathbf{T}Ax \leq \mathbf{T}b$ is equivalent (possesses the same optimal solutions) to $Ax \leq b$? If the $\mathbf{T}$ matrix exists and is not an identity matrix, the LP structural forms are not identified.

The reduced-form relations of an LP model are given by the quadratic loss criterion (2). In this case, $\mathbf{x}_a = \mathbf{P}\mathbf{w} + u$, $1 = \mathbf{s}'\mathbf{w}$, $\mathbf{w} \geq 0$, constitutes the LP reduced forms. Hypothesis testing, associated with these reduced forms, can be interpreted as a validation procedure of the LP specification. If the LP model is identified and the difference between the sample observations $\mathbf{x}_a$ and the projection $\mathbf{P}\hat{\mathbf{w}}$ is not statistically significant, one can conclude that the LP specification "explains" the behavior of the economic agents whose decisions are revealed by the vector $\mathbf{x}_a$. In other words, the LP model is validated. If the difference $(\mathbf{x}_a - P\hat{\mathbf{w}})$ is statistically significant, the LP model probably is not appropriate, and an alternative formulation should be sought. This is no different from the conclusion to be derived from econometric studies.

As with econometrics, a high level of "goodness of fit" cannot be taken as an exclusive index of model validity. On the other hand, the structure of LP studies is usually given a more explicit and (perhaps) thorough consideration than with econometric models. Thus, a high level of "goodness of fit" and a thoughtful specification of the LP structure and its identification may provide convincing support for not rejecting the model. Conversely, a low level of "goodness of fit" could induce the researcher to search for a better specification of the structural LP relations.

Multiple Optimal Solutions and Economic Equilibrium

The existence of multiple optimal solutions may serve, in principle and by itself, as a validation of economic models analyzed by linear programming. Consider, for example, profit-maximizing entrepreneurs who are assumed to operate in a perfectly competitive environment using homothetic technologies. If these assumptions hold, it is well known that first-order conditions imply that inputs are used in constant proportions to each other. The expansion path is a ray. In empirical data, these necessary conditions (expressed as exact or quasi-linear dependence) generate multicollinearity, usually disliked by the econometrician. Doll, however, in a perceptive reexamination of the problem, pointed out that "users of the(se) . . . model(s) who are dismayed to find multicollinearity among the 'independent' variables should be pleased because the presence of multicollinearity serves as a verification of their economic model" (p. 558).

This observation has its counterpart in linear programming models. If the firms analyzed by linear programming are assumed to operate under perfectly competitive conditions, and if the LP model is really capable of reflecting such an environment, one would expect many nondominated activities to be equally profitable, whether or not they are included in the optimal basis. This is because zero profitability is a long-run necessary condition for competitive markets. In general, commodities are available in these markets in larger number than the LP constraints of a single firm.

Let us reformulate this idea as follows: In a competitive situation, where there are many firms using essentially the same technology, one observes that similar firms produce different product mixes. In the absence of uncertainty, all activities are equally profitable and, therefore, it just happens that one firm chooses a particular combination of activities while others select a different mix. In LP terminology, this situation is characterized by zero relative loss not only for the optimal basic activities but also for those not in the basis. It causes the multiple optimal solution phenomenon. Hence, an extensive dual degeneracy may be interpreted as a validation of an LP economic model, where perfect competition and certainty prevail. Of course, it is unlikely that any large-scale LP model will exhibit zero profitability for all nonbasic activities. For this reason, validation of the model must take the form of a probabilistic statement.

Conclusions

This paper has accomplished several tasks. It has drawn attention to a neglected but important problem in empirical studies using an LP framework. It has outlined a more complete way of reporting LP results which includes not only the exact problem size but also an explicit statement about the

uniqueness (or multiplicity) of primal and dual solutions. It has suggested a plausible criterion for dealing with the choice created by the existence of multiple optimal and quasi-optimal solutions. It has argued for more formal validation procedures of LP models and for the reporting of a best-fit solution along with the other optimal solutions from which it is derived. In summary, it has suggested that the analysis of empirical problems using linear programming should not be conducted in the simplistic and mechanical way of the past thirty years. This is especially true when the goal of the study is either an efficiency judgement or the recommendation of a new policy.

Minimizing Mean Absolute Deviations to Exactly Solve Expected Utility Problems

Donald Johnson and Michael Boehlje

Quadratic programming (QP) procedures have been used widely in expected utility analyses. Yet, in a recent research project, we encountered numerous problems obtaining QP solutions.[1] Approximating techniques, such as MOTAD (minimization of total absolute deviations), MRC (marginal risk constrained programming), and separable linear programming (Hazell, Chen, Thomas et al.), were developed to overcome similar problems. Their merits have been determined primarily by comparing solution variances to QP solution variances, with all comparisons made at equal means. Most analysts feel that QP is preferable for small models; approximating techniques are only appropriate in large models when QP is impractical.

Proposition

In our work, we assumed that mean-variance analysis (or QP) is a means of solving an expected utility problem. We argue elsewhere that for certain symmetrically distributed variables, the QP solution includes those activities with maximum expected utility for that mean value (Johnson and Boehlje).[2] In other words, the set of activities with the lowest variance (for a given mean) also has the highest expected utility. Likewise, the validity of using alternate techniques should be based on how well they approximate expected utility solutions, not QP solution variances. To that end, we propose the following: if (*a*) two variates Y_1 and Y_2 are symmetrically distributed with the same means, and (*b*) density functions $f_1(y)$ and $f_2(y)$ are such that $f_1(y) \geq f_2(y)$ everywhere in the region $\mu - d < y < \mu + d$ (with strict inequality for at least one interval in the region) and elsewhere $f_2(y) \geq f_1(y)$, then $f_1(y)$ will have the smaller variance and also the smaller MAD (mean absolute deviations).

Figure 1 shows two density functions which satisfy the above conditions. Specific functions which will satisfy these conditions include the normal, double exponential, and triangular.

Proof

The function $f_1(y)$ has less weight in its tails than does $f_2(y)$; so variate Y_1 has a smaller variance than does Y_2 (Rothschild and Stiglitz). Since both variables are symmetric, the following inequality expresses the relationship between variances:

$$(1)\quad 2\int_{\mu}^{\infty}(y-\mu)^2 f_1(y)\,dy < 2\int_{\mu}^{\infty}(y-\mu)^2 f_2(y)\,dy, \text{ or}$$

$$\int_{\mu}^{\mu+d}(y-\mu)^2 f_1(y)\,dy + \int_{\mu+d}^{\infty}(y-\mu)^2 f_1(y)\,dy$$

$$< \int_{\mu}^{\mu+d}(y-\mu)^2 f_2(y)\,dy + \int_{\mu+d}^{\infty}(y-\mu)^2 f_2(y)\,dy,$$

and finally,

$$\int_{\mu}^{\mu+d}(y-\mu)^2\,[f_1(y) - f_2(y)]\,dy < \int_{\mu+d}^{\infty}(y-\mu)^2[f_2(y) - f_1(y)]dy.$$

Next, two nonnegative functions can be defined

$$g(y) = f_1(y) - f_2(y),\ \mu < y < \mu + d; \text{ and}$$
$$h(y) = f_2(y) - f_1(y),\ \mu + d < y < \infty.$$

Since symmetric variables have one half their probability in their right tail, the amount by which the probability mass of $f_1(y)$ exceeds $f_2(y)$ in the region $\mu < y < \mu + d$ is exactly offset by the amount by which $f_2(y)$ exceeds $f_1(y)$ in the region $\mu + d < y < \infty$, or

$$(2)\qquad \int_{\mu}^{\mu+d} g(y)\,dy = \int_{\mu+d}^{\infty} h(y)\,dy.$$

The above regions can each be subdivided into n smaller regions (indexed by i) such that

$$(3)\qquad \int_{g_i} g_i(y)\,dy = \int_{h_i} h_i(y)\,dy$$

for $i = 1, \ldots, n$.

For each of the regions of equal area, it is also true that

$$(4)\quad \int_{g_i}(y-\mu)^2 g_i(y)\,dy < \int_{h_i}(y-\mu)^2 h_i(y)\,dy,$$

Donald Johnson is an economist with the Caterpillar Tractor Company; Michael Boehlje is a professor, Department of Economics, Iowa State University.

Journal Paper No. J-9954 of the Iowa Agricultural and Home Economics Experiment Station, Project No. 2064.

[1] We used a RAND code which must solve in computer memory. Large models were costly to solve and, in one case, exceeded internal storage capacity. Also we were not able consistently to obtain feasible solutions until we changed default parameter specifications and tolerances. The default parameter values we used are available upon request.

[2] This requires that density functions meet the conditions outlined in the proposition and that utility functions have derivatives which alternate in sign, beginning with a positive first derivative.

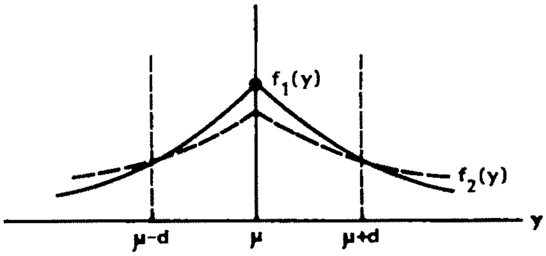

Figure 1. Density functions satisfying the proposition

since the $(y - \mu)$ values in the h_i regions are always greater than the $(y - \mu)$ values in the corresponding g_i regions. For the same reasons, it is also true that

$$(5) \qquad \int_{g_i}^{\infty} |y - \mu|\, g_i\,(y)\, dy < \int_{h_i} |y - \mu|\, h_i(y)\, dy$$

for all i. Then it can be shown that

$$(6) \qquad 2\int_{\mu}^{\infty} |y - \mu| f_1(y)\, dy < 2\int_{\mu}^{\infty} |y - \mu| f_2(y)\, dy,$$

or that variate Y_1 has smaller MAD than does variate Y_2.

Implications

If working with certain symmetric variables, e.g., a normal variate, then either minimizing MAD (using MOTAD) or minimizing variance (using *QP*) would lead to selection of the same random variate.[3] True, there is error in estimating variance through MAD, but one is really concerned with relative rankings among a set of variables. Theoretically, MOTAD would do this ranking as accurately as would quadratic programming.

In practice, QP and MOTAD solutions may not be identical. If true distributions are unknown, historical data are generally used to estimate parameters. In a QP model, sample estimates of the variance are used to find the lowest variance solution for each mean. Error can result, since the solution with lowest population variance may not be selected by the program. Likewise, in MOTAD, historical observations are used to calculate sample mean absolute deviations. Error again can result because sample estimates will not be the same as the population parameter.

Minimizing mean absolute deviations (or MOTAD) is theoretically as valid as quadratic programming in solving expected utility problems under the previously outlined assumptions. Theoretically, both techniques would give the same result; however, inaccuracies arising from using sample values may lead to different empirical results. The conditions outlined in this paper include normal distributions and quadratic utility functions as special cases—both frequent assumptions in agricultural risk studies.

[Received June 1980; revision accepted April 1981.]

[3] This would be true if the utility function were quadratic, negative exponential, or logarithmic.

Capital Gains versus Current Income in the Farming Sector: Comment

John P. Doll and Richard Widdows

In the December 1979 issue of this *Journal*, Melichar compares estimates of capital gains in agriculture to the returns earned by productive assets in agriculture. As a result of his analysis, which was based on data from the balance sheet calculations of Evans, Melichar concludes: "It thus appears that both recent real capital gains and those of 1954–67 are, in a sense, fully explained by the growth exhibited by the current return to assets" (p. 1090). These findings have special significance at a time when the "conventional wisdom" of the profession seems to be suggesting that recent land value increases are based on speculative forces rather than asset earnings. Melichar shows that when asset earnings are expected to grow then, "a significant portion of the total return to farm real estate necessarily takes the form of real capital gains" (p. 1091).

Melichar's analysis is based upon an asset valuation model that has as a key assumption the constant growth rate of earnings. The purpose of this comment is to extend the description of the model used by Melichar and thereby suggest some further tests of its applicability to agriculture.

The Valuation Model

Using the formulation presented by Harris in the same issue of the *Journal*, the present value of an asset that is to be held n periods is given by

$$(1)\quad V_n = \frac{(1+g)}{(1+d)} R_0 + \frac{(1+g)^2}{(1+d)^2} R_0 + \dots + \frac{(1+g)^n}{(1+d)^n} R_0,$$

where V_n is the present value, R_0 is the amount the asset earns at time zero, g is the expected growth rate in earnings over time, and d is the discount rate applied to future earnings. If the asset is to be held $n+1$ periods, then the present value can be written

$$V_{n+1} = \frac{(1+g)}{(1+d)} R_0 + \frac{(1+g)^2}{(1+d)^2} R_0 + \dots + \frac{(1+g)^{n+1}}{(1+d)^{n+1}} R_0$$

$$V_{n+1} = \frac{(1+g)}{(1+d)} R_0 + \frac{(1+g)}{(1+d)} \left[\frac{(1+g)}{(1+d)} R_0 + \dots + \frac{(1+g)^n}{(1+d)^n} R_0 \right]$$

$$(2)\quad V_{n+1} = \frac{(1+g)}{(1+d)} R_0 + \frac{(1+g)}{(1+d)} V_n.$$

In equilibrium, by definition $V_{n+1} = V_n = V_e$. Substituting V_e into (2) gives Melichar's first equation (p. 1088):

$$(3)\quad V_e = \frac{(1+g)}{(1+d)} R_0 + \frac{(1+g)}{(1+d)} V_e;$$

and solving for V_e gives Melichar's second equation,

$$(4)\quad V_e = \frac{(1+g)}{(d-g)} R_0.$$

The equilibrium value, V_e, is in fact the sum of the infinite series obtained by assuming that the asset produces into perpetuity. This can be rationalized from (1) as follows: At the end of n periods, the asset may be sold and the sale value discounted back to the present. But the sale value is determined by the earnings from time $n+1$ into the future. Each time the asset is sold, earnings are again extended into the future, and hence, without limit. As long as $d > g > 0$, the infinite series has the limit V_e. This limit can be derived directly (Van Horne, p. 22, and Reilly, p. 301).

Interpretation of Equilibrium

When interpreting the equilibrium, Melichar states: "For this asset, real capital gains arise in two ways. First, changes in the value of R, g, or d result in a new equilibrium value V, and the amount of change in V is a real capital gain. Second, if the growth rate g is greater than zero, the equilibrium value V rises each year even though the values of g and d are unchanged; that is, annual capital gains are an inherent feature of the equilibrium condition" (p. 1088).

John P. Doll is a professor of economics and Richard Widdows is a graduate assistant in economics at the University of Missouri-Columbia.

The authors are indebted to David H. Harrington and John E. Lee, USDA-ESS, for supporting their research on land values. Emanuel Melichar graciously pointed out a serious empirical error in an early draft of this comment, and the authors wish to thank him for his help and patience.

Equation (4) presents the equilibrium value of the asset, which is the sum of a convergent infinite series. This value is unique, given values for d, g, and R_0, where $d > g > 0$. V_e will increase as g and R_0 increase and decrease as d increases, but V_e will not change unless one or more of these three variables change. Viewed another way, if the realization of R_0 or expectation of d or g change at a given point in time, then V_e will change at that point in time. This would be comparative statics in the usual sense. Thus, Melichar's first conclusion above follows directly from equation (4).

Next, assuming that the expected growth rate g is realized each year, asset earnings would be $R_1 = (1 + g) R_0$ at the beginning of the second period, $R_2 = (1 + g)^2 R_0$ at the beginning of the third period, and, in general, $R_t = (1 + g)^t R_0$ at the beginning of the tth period. Extending this reasoning, the equilibrium value of the asset through time would be

$$V_{et} = \frac{1 + g}{d - g} R_0 (1 + g)^t, \tag{5}$$

where V_{et} is the value of the asset at the beginning of year t, and the first value of t is zero. This formulation follows directly from the discussion following equation (4), where expectations are continually realized.

The panels in Melichar's table 2 (p. 1090) can be derived directly from equation (5). The values in panel A, equilibrium asset value per dollar of current return, are given by the ratio $[V_{et}/R_t = (1 + g)/(d - g)]$. This is a concept using earnings that is similar to the "dividend" multiplier defined by Reilly (p. 265) as $[V_{et}/R_{t+1} = 1/d - g]$, which compares earnings at the end of the period to asset value at the beginning of the period.

Panel B, annual capital gain as a percentage of asset value, is given by

$$\frac{V_{e(t+1)} - V_{et}}{V_{et}} = g.$$

Panel C, annual current return as a percentage of asset value, is given by $[R_{t+1}/V_{et} = (d - g)]$, when annual current return is assumed to measure earnings at the end of the period. It is the inverse of the earnings multiplier and, as Melichar suggests, is important because it determines how the total return is divided between a capital gain and a current return.

Finally, Panel D, annual capital gains as a percentage of annual current return, is given by

$$\frac{V_{e(t+1)} - V_{et}}{R_{t+1}} = \frac{g}{d-g}.$$

The results for Panels B, C and D must be converted to percentages.

To review the assumptions, equation (1) requires, in addition to the usual assumptions for discounting future returns, the assumption of a constant growth in earnings for a period of length n. The sale value of the asset in period n could be added to the equation and discounted back to the present. No stipulation need be made concerning the relative magnitudes of d and g. To obtain equation (4), the additional assumptions required are that the growth rate g is perpetual and that d, which is defined as the discount rate or the required rate of return, must exceed g. If estimates of d are based on opportunity cost, such as a market rate of interest, then determination of V_e using (4) requires that these external rates of interest exceed the rate of growth of earnings within the firm into perpetuity. Investors might use equation (4) to revalue assets annually, revising their estimates of d, g, and R_0 as appropriate. But, equation (5) will result when these expectations are perpetually stable.

Evaluating the Model

Equation (4) would appear to be difficult to test using time-series data. If investors change their expectations of d, g, and R_0 on an annual basis, then the equilibrium value of the asset will change accordingly. Increases in land values, such as those experienced recently, could result from expectations of increased earnings, increased growth in earnings, or both.

Testing equation (5) should be easier. If expectations of all quantities are stable, then examination of equation (5) suggests that asset values should grow at the same rate as asset earnings.

As a first step, we computed the growth rates for asset earnings and asset values for the time periods selected by Melichar in table 1 (p. 1089). (The data were obtained from the more detailed paper presented by Melichar at the summer meetings.) Following his suggestion, growth rates for returns were computed from the value in the year preceding the period (except for 1954–60) to the value in the last year of the period, while growth rates for assets were computed between the first year in the period and the 1 January value of the first year following the period. The growth rates obtained were as follows:

	Earnings (%)	*Asset Values*
1954–60	3.4	5.0
1961–67	8.0	5.2
1968–71	6.7	5.3
1972–78	13.4	13.2

From a value standpoint, real estate is the major component of asset values—approximately 90% in 1978. Thus, growth rates in real estate values differ only slightly from the growth rates in asset values.

Returns in agriculture are quite variable, while asset values (with isolated exceptions) have increased steadily over the past thirty years. Thus, the growth rates for earnings presented above may depend unduly upon the endpoints of the periods selected. To avoid this, we estimated growth rates using least squares regression. Lacking better crite-

ria and to avoid excessively small samples, we estimated growth rates for each decade and the entire period. The resulting growth rates were the following:

	Earnings		*Asset Values*
		(%)	
1950–59	−5.3		3.7
1960–69	7.3		4.8
1970–79	8.7		11.5
1950–79	6.9		6.1

Thus, while growth rates differed markedly within decades, growth rates for earnings and assets were remarkably similar for the thirty-year period.

The estimates presented suggest that asset earnings and asset values in agriculture are not perpetually growing at the same rate. If they were, their growth rates would be invariant to the time period selected. Moreover, the regression results suggest that asset earnings grew about three percentage points faster than asset values in the sixties, but the growth rates were reversed in the seventies. The more rapid growth of earnings in the sixties might be attributed in part to a recovery from the depressed earnings of the fifties. But, because the time periods were selected arbitrarily, we would hesitate to draw strong conclusions, even though the least-squares estimates are less susceptible to the selection of endpoints.

The key to all of this would appear to be the manner in which investors form expectations. It seems to us that Melichar is correct in concluding that growth in earnings is having an important (and hitherto overlooked) effect on asset values. But, we also believe equation (5) may provide too restrictive a view of what actually is happening. Investors may be reformulating growth rates, as well as the value of initial earnings, on an annual basis in such a way to cause the more rapid growth rate in asset values evidenced in the seventies. Some of the models that have been developed recently, for example by Lee and Rask, Harris and Nehring, or Plaxico and Kletke, which consider many factors, such as capital gains taxation rates, might be used to shed light on why asset values grew faster than asset earnings in the seventies.

As an alternative, we examined Melichar's results using the more traditional analyses presented in finance textbooks. Such analyses are commonly based on the assumption that investors value assets using equation (4) and reevaluate expectations annually.

The attached table 1 was developed from Melichar's data. The value of production assets on 1 January, used as estimates of V_e, were divided by the annual earnings of production assets, representing R_1. Assuming that investors do use the earnings growth model to place values on assets, then the numbers in the table represent estimates of the coefficient $(1/d - g)$, the earnings multiplier referred to above.

Table 1. Value of Farm Production Assets per Dollar of Earnings

Year	Assets/$	Year	Assets/$	Year	Assets/$
1950	16.1	1960	33.2	1970	24.4
1951	16.1	1961	27.8	1971	24.4
1952	20.6	1962	25.9	1972	17.8
1953	30.1	1963	27.0	1973	9.9
1954	29.3	1964	30.9	1974	16.0
1955	37.1	1965	21.2	1975	18.7
1956	36.1	1966	20.3	1976	28.6
1957	33.5	1967	26.3	1977	31.1
1958	22.7	1968	27.8	1978	22.7
1959	44.6	1969	23.8	1979	22.1

Source: Melichar.

In 1979, each $22.1 of agricultural assets earned $1 of income. This ratio was lower than 22 only nine times in the previous twenty-nine years. In fact, the asset/earnings ratio was much higher in the late fifties when it moved above 30 four times and achieved an all-time high (in the sample period) of 44.6 in 1959. From this, we would have to conclude that if assets were overvalued in 1978 and 1979, then they also have been overvalued most years since 1950.

Another application uses the equilibrium value equation to determine what Van Horne, on page 22, calls the "expected" return. From equation (4), the expected return is

$$d = \frac{R_1}{V_e} + g,$$

which is the economists' discount rate or required rate of return. Again, assuming equilibrium, earnings as a percentage of production assets can be used to estimate the ratio R_1/V_e. These returns are the inverse of the numbers in our table, expressed as percentages. The growth rate in earnings estimated by regression for 1970–78 was 8.7%. This is, of course, dependent upon the period selected, and may not represent a time period used by investors. As an alternative, we computed the growth rate between the average earnings for the decades of the sixties and the seventies. Assuming that the averages are also separated by ten years, they grew at about 10%. Using these as high and low estimates, the "expected" return for agriculture was between 13.2% and 14.5% for 1979. Further, it could have been as high as 20% in 1973 and as low as 11.9% in 1977.

Thus, another way to interpret the application of the earnings growth model would be to say that if, in 1979, an earnings growth rate of 10% and a discount rate of 15% prevailed, then production assets were not overvalued relative to earnings. Of course, d and g are not unique; the pairs d = 0.10

and $g = 0.05$ or $d = 0.05$ and $g = 0.0043$ also would result in a valuation of twenty-two times earnings. Thus, the lower the farmer's discount rate, the lower must be the growth in earnings to justify a given value level, and vice versa.

Finally, rather than using equations (3), (4), or (5), equation (1) might be used directly to evaluate the applicability of the earnings growth model to agricultural data. Equation (1) does not require the assumption of an infinite time horizon, a perpetual growth rate, or even the assumption that d exceeds g. Reilly suggests (p. 373) that g will exceed d in growth firms, but only for short periods, because no firm can outgrow the market perpetually. Van Horne (p. 23) provides a variation of equation (1) that permits the use of different growth rates during transitional periods. Thus, while the equations (3), (4), and (5) provide convenient mathematical summations of the valuation problem, equation (1), which would require computer solutions, appears to offer a potential for solutions richer in interpretation. The results, of course, would depend on how well researchers could approximate the manner in which investors form expectations of the parameters of the model.

Capital Gains versus Current Income in the Farming Sector: Reply

Emanuel Melichar

Doll and Widdows (D-W) describe the model that characterizes the relationship between asset earnings and market value and show how the rates of return from earnings and capital gains are linked to earnings growth rate, relationships illustrated in table 2 of my original article. Readers studying may draw upon our combined text, algebra, and tables.

This asset valuation model is no stranger to many agricultural economists. I originally came to it by simplifying land valuation models presented by Lins (p. 15) and Willett and Wirth (pp. 19–20), models designed for analysis of individual land purchases and including tax rates, planning periods, inflation, and terms of debt financing (variables which D-W suggest might be considered in future analyses). Both models also differed from the one discussed here in allowing users to enter one projected growth rate for earnings and, if desired, a different—presumably higher—projected growth rate for land prices. This reflected the general impression that land prices had been rising faster than earnings—a view apparently based on the divergent trends of the USDA's net farm income and land price series rather than on actual investment experience. While Willett and Wirth advised users of their valuation formula: "If land use is restricted to agricultural enterprises, the change in market price should be similar to the rate of change estimated for annual agricultural returns" (p. 11), they had stated earlier that "there has been a growing disparity between farmland value and earnings from that farmland" (p. 1).

After showing that net farm income does not measure asset earnings and that the long-term growth rate of actual asset earnings may be even higher than that of asset values or farm land prices (Melichar 1978), the model demonstrates that this earnings growth provides the chief explanation for two empirical observations that have puzzled economists: (*a*) the rise in real land prices and (*b*) the relatively low rate of current earnings of farm assets (that is, the relatively high asset/earnings ratio). The first outcome is self-evident; an asset price should rise or fall at the same pace as its earnings, *ceteris paribus*. The second result is logically more subtle, the arithmetic is simple, and the policy implications are remarkable.

To know whether the model, its empirical consequences and their policy implications are of practical significance, one needs to know how the growth record of earnings compares with that of assets. This Doll and Widdows empirically explore. It is enlightening to note here that the general nature of the comparative behavior of these series has been implicitly known to agricultural economists for many years and that it has been implicit in a major empirical finding and teaching of the profession. Have we not taught that the rate of return has remained at 3%–4%, on average, for several decades, and implicitly taught that earnings have risen as fast as equity? Have we not observed an upward tendency in the ratio since its post-Korean War lows and thought this trend logical in view of the improving relationship between aggregate demand and farm production capacity? We have implicitly observed that earnings have risen somewhat faster than equity over the whole period and that equity recently has been priced at a lower multiple of earnings than in the mid-1950s. Have we not been aware of the sizable rise and fall in the rate of return over certain periods, particularly during the Korean War and again in 1972–77? We have known that rates of change in earnings and assets have differed greatly over certain shorter periods, even as their longer-term trends have been similar. To transfer this body of knowledge to the present discussion, we need to note that adding debt to equity and interest to earnings does not greatly alter the general level, trend, or cyclical behavior of either series or their ratio (see chart 2, p. 200, Melichar 1978).

Hence, the empirical record scrutinized by D-W already has been explored and accepted by our profession. With the asset valuation model seen as consistent with the asset and earnings data, we now can confidently state that the increase in farm asset value reflects increased farm earnings, and that the low present earnings rate (or high asset/earnings ratio) reflects the expectation of continued future earnings increases. (This is an important correction to a similar statement by Schertz and Harrington, p. 61.) Thus, there is urgent need to study the causes of past earnings growth, prospects for future growth, and policy implications of various growth rates.

Before elaborating on these suggestions, however, a few specific comments are in order on

---

Emanuel Melichar is a senior economist in the Division of Research and Statistics, Board of Governors of the Federal Reserve

asset earnings and asset values. Their first comparisons are made in nominal terms for the same periods for which I had reported similar real-term comparisons; thus our results are similar, with our reported rates differing mainly by the rate of general price inflation by which I had deflated my asset and earnings variables. D-W note that the relationship between the growth rates of assets and earnings changes from one period to the next. This is hardly surprising, however, as I had selected those specific time spans "on the basis of differences either in the growth rate of the current return . . . or in the relative importance of capital gains" (p. 1088). Furthermore, D-W employ a technically inferior asset variable, and thus my original comparisons might be preferable. The latter deficiency also occurs in their second set of comparisons, in which decades are the periods examined and least-squares regression is used to estimate growth rates. More seriously, this second set produces misleading values for earnings growth in two of the three decades because of the presence and timing of a large cyclical swing in earnings within each decade.

The technical flaw in calculating growth rates for unadjusted asset values as D-W did is that such values rise or fall as a result of net investment and intersector transfers as well as of price changes; and, for our purpose, the growth rate desired is that due to asset price changes only. For their calculations in nominal terms, D-W should have constructed an asset variable whose values change only as nominal capital gains or losses are experienced. In my parallel work in real terms, I reported the average rate of real capital gains on physical assets (table 1, column C × column B). In addition, because only the real estate component of farm assets is likely to reflect capitalized earnings, and because in some periods there are noticeable differences between rates of price change for total assets and real estate, I also reported the average rate of real capital gains on real estate alone (column D). (Real estate comprised only 80% of total farm production assets in 1978, rather than 90% as D-W state. Earlier in the 1950–79 period, proportion was as low as 66% [Hottel and Evans, p. 63]. Thus the growth rates of adjusted assets and real estate probably differed somewhat.) D-W may not have recognized that these results were asset growth rates, as they do not mention them. Adjustment for net investment and transfers was minor relative to price change size; thus our results are similar. For the specified time, we both find that, as compared with the earnings growth rates, those of assets were somewhat higher in 1954–60, considerably lower in 1961–67, somewhat lower in 1968–71, and about the same in 1972–78.

The misleading earnings growth rates D-W report for the 1950s and 1970s are more serious because they are led to believe that asset growth in the latter decade significantly exceeded earnings growth. While such divergence could have resulted from a change in expected real earnings growth or in the real discount rate (required rate of return), this does not appear to have occurred. The years of exceptionally high earnings, 1972–74, occur in the first half of the decade; the two years of lowest earnings occur in the second half. When a semilogarithmic least-squares regression line is estimated through this up-down-up cycle, its slope is flattened and both slope and position are unrepresentative of the decade's earnings. It also differs from the common view of the longer-term course of earnings in that period, which would be instrumental in asset pricing. Few persons thought that earnings could be sustained at the exceptional level of 1973; later low earnings of 1976–77 were viewed similarly, as a downside aberration. In 1978–79 earnings seemed to be "on track." Hence, I chose to draw an earnings trend from the 1971 to the 1978 value, a trend which has a growth rate about equal to that of assets and real estate prices.

The same point may be made through an alternative approach facilitated by D-W's table 1. If asset values did rise faster than earnings in the 1970s, as D-W conclude, then the asset/earnings ratio in their table 1 also must have risen. In fact, given their least-squares results, the ratio should have risen by 2.9% annually (the difference between their least-squares asset and earnings growth rates). Does inspection of their data indicate that the asset/earnings ratio rose by almost one-third over the decade? No, a reasonable impression is that, after the gyrations of 1972–77, the ratio remains at about the level at which it entered the decade, or perhaps has fallen slightly. Thus the least-squares result, caused by the presence and position of the severe earnings cycle, is misleading. Similarly, if the asset/earnings multiple has not risen, neither the expected real earnings growth rate nor the real discount rate has changed (with the possible exception of offsetting movements).

Future work on these past empirical relationships should employ recently revised USDA earnings series (Hottel and Evans; USDA, pp. 53–54), presenting data back to 1940. The return to production assets, although calculated as a residual, is probably about as reliable as the total net farm income series, since actual farm wage rates and management fees are available for use in calculating imputed charges for operators' labor and management. In addition, one can take comfort in knowing that studies using landlords' rent rather than residual earnings have consistently produced similar findings in stable agricultural areas (Reinsel, Dobbins et al.). The reliability of the asset series basically depends on the accuracy of the USDA survey of farm real estate prices, but in addition there is some uncertainty about the appropriate adjustment for net investment. The balance sheet of the farming sector, on which I based my capital gains calculation, shows that the physical stock of farm real estate increased by 5.5% 1960–78 (Evans, p. 8),

whereas another account indicated net disinvestment of $30.8 billion (Evans, p. 40). In addition to using revised and improved data, future analyses might try to employ valuation models that include considerations such as tax rates and financing terms.

At this stage in the development of our new insights there seems to be more to be learned from investigating past causes and future prospects of real asset earnings growth. In the mid-1960s, Chryst, and Herdt and Cochrane almost found the key to the asset/earnings relationships but then missed it and concluded that government price support and supply reduction programs, when combined with ongoing cost-reducing, output-increasing technological advances, tended to increase asset earnings. The authors, however, were unable to break through their entrenched image of a flat net farm income. Chryst decided that the capitalization rate must have been falling, while Herdt and Cochrane wrote that income gains were merely "expected" increases which vanished when capitalized. We can now set aside these erroneous interpretations and appreciate anew the analyses of rising asset earnings. Similar studies of the past decade are needed to provide information about the relative importance and probable trends of factors more recently responsible for an increase in real asset earnings. Again, difficulties posed for time-series analysis by the severe earnings cycle might require such work to be couched in terms of a comparison of, say, 1970–71 with 1978–79.

Policy implications of the new insights also need to be developed, both private and public. From 1954 to 1979, the total real rate of return to farm assets averaged about 8%, providing a rough estimate of the average real discount rate, or required rate of return, of farmland purchasers. If no real earnings growth were expected, farm real estate would sell at about 12.5 times earnings, to yield the required 8%. It is selling at double that multiple, yielding only 4%, and buyers implicitly expect that earnings will continue to rise at a long-term annual rate of 4%. They assume any risk of reduction in growth rate would lead to a capital loss as the land market became aware of it, while increase in the growth rate would give them a windfall gain. We need assessments of the nature of this risk, particularly by nonoperator investors who are increasingly encouraged to consider initial farm real estate purchases.

Perhaps public farm policy is not now as instrumental in maintaining asset earnings growth as earlier studies indicated, but the combined effect of farm programs such as storage loans, deficiency payments, disaster assistance, and export promotion may still be considerable. To the extent that these programs cause the earnings growth rate to be higher than it would otherwise be, they simultaneously increase the real price of farm output and reduce the rate of current earnings to assets, compared with levels that otherwise would have prevailed. The first effect is financially harmful to the general public; the second is not welcomed by farmers. It appears that both groups would benefit from a move to lower farm earnings growth, but in reality the process of so doing would be painful for farmers and farm landlords. In the short run, the rate of current earnings would first decline, because the response of asset values probably would lag the earnings change; then, when asset values did adjust, farm owners would experience capital losses. One could conclude easily that our political institutions would not care to undergo this experience. Perhaps our policy analysts can devise a path to lower earnings growth that will be tolerable to asset owners who have paid in advance for the higher growth rate.

Economic conditions and trends may be moving farm policy in this direction in spite of the inherent dilemma. Some government contributions to maintaining a high real growth rate of farm asset earnings are more acceptable to the public than others. First, policies helping real earnings to grow at a given rate in one sector are more easily accepted or tolerated if real economic growth in general equals or exceeds that rate. Otherwise, the resulting relative transfer of real wealth to the assisted sector requires more justification as a net contribution to the general welfare. Next, it is likely that such transfers are more easily tolerated if the underlying earnings growth results mainly from cost-reducing productivity gains rather than from increases in the real price of the sector's output. Finally, wealth transfers are more tolerable if the assisted economic units are relatively small and/or poor, or are so perceived.

The first two conditions appear to have turned against agriculture during the past decade. General economic growth slowed, and farm earnings growth became more dependent on real increases in output prices. The third condition is now also coming into play. Nearly fifty years of compounded growth in real wealth, abetted by consolidation of units and recently by reduction in estate taxes, have made many farm families rich from the perspective of the general public. There may be a significant risk of reduced government assistance for agriculture, or the aid may shift toward more subtle forms such as export promotion. Studies of these matters from our new analytical perspective should be interesting.

Economic Welfare and Food Safety Regulation: The Case of Mechanically Deboned Meat: Comment

J. Bruce Bullock and Clement E. Ward

In a recent *Journal* article, McNiel estimated the welfare effects of USDA regulations governing the production and use of mechanically deboned meat (MDM). McNiel estimated a set of monthly supply and demand parameters to calculate the social costs of regulations. He then calculated the social cost of regulations that limit the output of MDM to 20% of processed meats, excluding ground meat, instead of all MDM economically recoverable by existing technology.

Two problems with the McNiel analysis invalidate his estimates of social costs. First, the data series used to estimate the demand and supply parameters is inappropriate. Second, the regulations limiting MDM usage will not become a constraint on total MDM production and will not generate social costs.

MDM Regulations

Three regulations affect the production and use of MDM from beef and pork carcasses:

(*a*) Amount of MDM in final product: MDM can make up no more than 20% of the total meat portion of a finished product. MDM is prohibited in ground beef and a few other products.

(*b*) Final product labeling requirements: a product containing MDM must contain a statement on the label which says "mechanically processed (species) product" in letters at least half the size of the product name. The label also must state, "contains up to _____% of powdered bone." This must be no less than one-fourth the size of the product name.

(*c*) MDM protein, fat, and calcium content: MDM can contain no more than 30% fat, 0.75% calcium, and no less than 14% protein.

Each of these has a different potential impact on the production and social costs of MDM.

McNiel's Analysis

McNiel notes that beef and pork are consumed either as table cuts or as processed meats. MDM is a potential ingredient in processed meats. Thus, for analysis it is desirable to partition the demand for beef and pork into that for table cuts and that for processed meats. Unfortunately, monthly data do not report the mix of table cuts and processed meats consumed.

To solve this problem, McNiel disaggregated total beef and pork consumption into "two components, table cuts and processed meats, using share estimates obtained from USDA consumption surveys which were consistent with the market shares used in constructing the price series" (McNiel, p. 4). Thus, the following relationship exists in the McNiel consumption data for both beef and pork:

$$QTM = \alpha MC,$$
$$QPM = (1 - \alpha)MC;$$

hence,

$$QPM = \left(\frac{1-\alpha}{\alpha}\right)QTM,$$

where QTM is quantity of table meat consumed, QPM is quantity of processed meat consumed, MC is $QTM + QPM$, and $0 < \alpha < 1$ is the table cut proportion of total consumption.

Consequently, the McNiel data maintain table cuts and processed meats in fixed proportions in all time periods. Based on the footnote to McNiel's table 2, the table cuts account for 60.8% and 77.6% of total beef and pork consumption, respectively. Thus $QPB = 0.64QTB$ and $QPP = 0.29QTP$ in McNiel's data series. These data cannot be used to estimate demand and supply parameters that purport to show the impact of changing proportions of table and processed meats. Thus, the elasticities in table 2 of McNiel's paper are not meaningful.

According to McNiel's analysis, the regulation limiting the MDM content of processed meat to no more than 20% would cause the total production of mechanically deboned beef (MDB) to be only about one-third of the economically feasible production level. Similarly, mechanically deboned pork production (MDP) would be only about one-sixth of the feasible level of production. However, it is physically impossible for the industry to produce enough MDB or MDP for the 20% restriction to become an effective constraint on total MDM production.

McNiel estimates that 39.2% of beef is consumed as processed meat. Agnew reports that ground beef accounts for about 57% of processed beef consump-

---

The authors are associate professors, Department of Agricultural Economics, Oklahoma State University, Stillwater, Oklahoma.
Journal Article No. 3857, Oklahoma State University Agricultural Experiment Station, Stillwater.

tion. Thus, 16.9% of beef consumption is processed meat to which MDB could be added under current regulations. Field reports that the upper limit on MDB production is about 16 pounds per carcass. This would be a 2.7% increase in beef supplies assuming average 600-pound carcasses. Therefore, at a maximum, MDB could account for $\left(\frac{2.7}{16.9 + 2.7}\right) = 13.7\%$ of processed beef supplies, excluding ground beef. Similarly, MDP could account for no more than about 15% of processed pork production. Field also reports that the upper limit on MDP production is about 4 pounds per 137-pound carcass. This means that MDP will increase pork supplies by 2.9%. If 25% of processed pork is fresh ground (probably an overestimate), then MDP can account for at most $\frac{2.9}{16.8 + 2.9} =$ 15% of processed pork production. Consequently, the 20% regulation is not a restriction on total MDM production.

The inability of the McNiel model to assess correctly the impact of the MDM regulations indicates that it is improperly structured. This, plus inappropriate estimates of demand and supply elasticities, indicates that McNiel did not develop useful estimates of the welfare effects. Although McNiel did not develop valid estimates of the social costs, he addressed an important issue for consumers and the meat processing industry.

Economic Nature of Problem

Use of the MDM technology makes it possible to increase meat supplies without increasing the number or weight of animals slaughtered. The social costs of restricting the use of this technology are illustrated in figure 1.

The consumer demand for meats (composite of table cuts and processed meats) is represented by DD'. Without MDM technology, S_0 units of meat can be produced from the number of animals slaughtered during this period. Meat production can be expanded to S_m if MDM technology is used. The per unit cost of raw materials plus total costs of operating MDM equipment is represented by S_0H. The area $HABE$ represents the net social value of the MDM technology. The social cost of restricting the use of the technology is the portion of the social value of the technology that cannot be attained.

The 20% restriction will not become a constraint on total MDM output and hence will generate no social costs. However, it could be an effective constraint for some processed products. The product-labeling restriction is the current regulation that limits MDM production. Meat processors think that current labeling requirements project a negative image of their product to consumers. Therefore, they refuse to use MDM. Thus, all social costs of

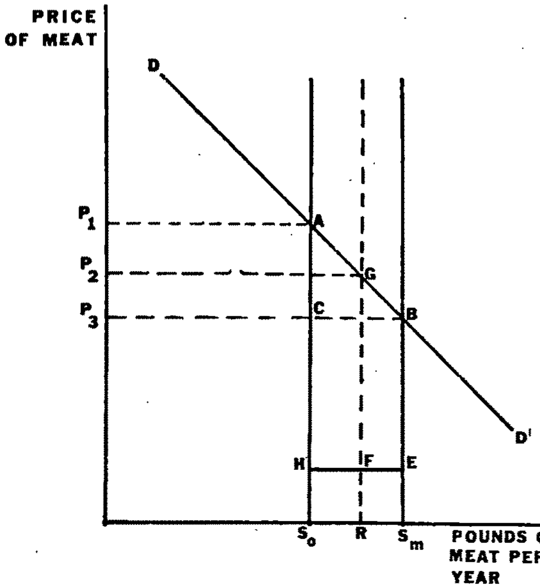

Figure 1. Illustration of impact of fat and protein content restrictions on the net economic value of MDM technology

current regulations ($HABE$ in figure 1) are attributable to the labeling requirements. "There is no basis for expecting that the long-term use of MDM would pose health hazards or that the long-term effects would be any different from other processed food products" (USGSA p. 26418). Consequently, there is no medical justification for this type of regulation. The success of a processed meat product in the marketplace depends on repeat purchases by satisfied customers. Competition will weed out products with too much MDM to satisfy consumers. Although this regulation does not generate social costs at present, it might in the future. Continuation of the 20% limit could preclude development of new products quite acceptable to consumers. Hence, the public interest would be served by removing this regulation.

The restriction on fat, protein, and calcium content of MDM is currently less important since labeling requirements reduce MDM production to zero. However, if the labeling restrictions were modified, the fat and protein regulations could become effective constraints on MDM production. MDM produced from fed cattle, upper grade cows, barrows, gilts, and sows either exceeds fat content restrictions or fails to meet minimum protein requirements. Thus, a considerable portion of the potential MDM supply will not be produced because of the fat and protein restriction even if the labeling requirements are removed. The potential impact of this restriction on MDM production likely will increase as boxed beef production expands, increasing the raw materials from fed cattle available for mechanical deboning.

If the labeling restrictions did not exist, fat content restrictions would restrict MDM output to S_cR rather than the economically feasible level S_oS_m (figure 1). Consequently, a portion of the potential MDM benefits would not be realized because of the restriction. The area *FGBE* represents the social cost associated with the fat and protein restrictions if the labeling regulations were removed. Estimates indicate that removal of the labeling restrictions would recover only about 30% of the social costs of the regulations unless the MDM fat and protein content restrictions also are removed (Bullock and Ward).

Current regulations establishing limits on MDM content in final products and maximum fat content of MDM provide the consumer no more protection than is already available through existing regulations and the economic realities of the marketplace. Moreover, these regulations impede the efficient use of resources and generate social costs without generating social benefits. Social welfare would be improved by eliminating them.

Potential Impacts of MDM Technology on Livestock Prices

The use of MDM technology both increases and decreases the value of beef and pork carcasses. The value of a carcass is increased because several pounds of edible MDM are recovered that otherwise would be sold as inedible byproducts. However, widespread use of MDM technology will increase total supply and, hence, reduce the price of meat, *ceteris paribus*. Thus, the net impact of MDM technology on carcass value (and therefore the price of livestock) depends on the relative magnitudes of these two impacts.

The impact on net farm value of 100 pounds of carcass of introducing MDM technology is identified by the following equation:

$$(1) \quad \Delta V = W_m{}^o(P'_m - P_m{}^o) + \Delta W(P'_m - P_b - C_d),$$

where ΔV is the change in net farm value per 100 pounds carcass weight (\$/cwt), $W_m{}^o$ is the pounds of meat marketed per 100 pounds of carcass if MDM technology is not used, ΔW is the additional pounds of carcass marketed as meat (not marketed as bone) per 100 pounds of carcass if MDM technology is used, $P_m{}^o$ is the price of meat that would exist if MDM technology is not used, P'_m is the price of meat as a result of using MDM technology to increase meat supplies, P_b is the price of bone (opportunity cost of marketing MDM is meat rather than bone),[1] and C_d is the cost of owning and operating MDM machinery (\$/pound of MDM).

[1] The price of raw materials is assumed to be the same whether or not MDM technology is used. Widespread use of MDM technology should increase P_b as the amount of this product sold is reduced. However, the magnitude of this impact would likely be quite small and is ignored for purposes of this discussion.

The first term of equation (1) measures the decrease in carcass value because of the reduced price of meat resulting from expanded supplies. The second term shows the net gain in value of ΔW pounds of MDM marketed as meat rather than bone. MDM production will be economically feasible if $(P'_m - P_b - C_d) > 0$, and there will be a net increase in social welfare from the use of MDM technology as illustrated in figure 1. However, depending on the value of ΔW, the introduction of MDM technology may result in a welfare transfer from producers to consumers.

The value of ΔV functions as a shifter of the derived demand for live animals. The determinants of the value of ΔV are identified by further examination of equation (1). By definition,

$$P'_m - P_m{}^o = \Delta P = \frac{\Delta W}{W_m{}^o} \cdot \eta \cdot P_m{}^o \leq 0,$$

where $\eta < 0$ is the price flexibility of meat with respect to the quantity of meat. Substituting this for $P'_m - P_n{}^o$ in the first term of equation (1) and multiplying the second term by $P_m{}^o/P_m{}^o$ results in

$$(2) \quad \Delta V = (\Delta W \cdot \eta \cdot P_m{}^o) + (\Delta W \cdot kP_m{}^o),$$

$$\Delta V = \Delta W \cdot P_m{}^o(\eta + k),$$

where $k = \dfrac{P'_m - P_b - C_d}{P_m{}^o}$ is the incremental net value of MDM expressed as a portion of $P_m{}^o$. This ratio has no particular economic interpretation. However, $1 > k > 0$ since $P'_m - P_m{}^o = < 0$, $P_b > 0$, and $C_d > 0$, and because $(P'_m - P_b - C_d) > 0$ if MDM technology is economically feasible.

If $\Delta V = 0$, the derived demand for livestock will not shift and the introduction of MDM technology would have a neutral impact on livestock producers. If $\Delta V > 0$, the derived demand for livestock will shift to the right and generate higher livestock prices, *ceteris paribus*. However, if $\Delta V < 0$, the derived demand for livestock will shift to the left and generate lower livestock prices.

Production of mechanically deboned beef and pork are both technologically and economically feasible (Bullock and Ward). Thus, any relaxation of MDM regulations will expand meat supplies, reduce meat prices, and expand social welfare. However, if $|\eta| > 1$, as most published estimates indicate, the widespread use of MDM technology will result in some amount of welfare transfer from producers to consumers.

Economic Welfare and Food Safety Regulation: The Case of Mechanically Deboned Meat: Reply

Douglas W. McNiel

As Bullock and Ward point out in their "Comment," there are three major types of regulations which may presently be constraining MDM production and use—ingredient standards, use limitations, and labeling requirements. Bullock and Ward attempt to analyze and evaluate the separate economic effects of each type of regulation so that we may better understand the benefits and costs associated with various alternative regulations. Unfortunately, both the theoretical and empirical basis of their analysis have such serious deficiencies that only limited progress is made toward this objective.

Supply-Side Constraints

Regulations establishing ingredient standards and use limitations for MDM are primarily supply-side constraints. The correct methodology for analyzing such supply-side regulatory constraints is presented in my original work (McNiel). Bullock and Ward have attempted to improve upon this analysis with more detailed estimates of the effects of each type of regulation on the supply of (processed) meat . . . more on this later.

Demand-Side Constraints

While Bullock and Ward indicate that these supply-side regulations could become a constraint in the future, they argue that "all social costs of current regulations . . . are attributable to the labeling requirements." The impact of the labeling requirements for products containing MDM was not analyzed in my original work. Since most of the controversy over MDM regulation centers on labeling, additional analysis would be useful. However, evaluation of the labeling regulations requires a more complex methodology, not found in Bullock and Ward's analysis. The methodology they employ to evaluate this demand-side constraint does not differ from the methodology employed to evaluate the supply-side constraints. Unfortunately, the supply-side methodology alone is not appropriate for this extension nor adequate to support their argument.

Labeling regulations for products containing MDM have inherent demand-side implications which Bullock and Ward do not take into account when analyzing their attendant welfare effects. To attribute the entire welfare loss from MDM regulation solely to the labeling requirements, one must assume that (*a*) consumers with perfect information would regard processed meats containing MDM as homogenous with other processed meat products not containing MDM, and (*b*) currently required labels mislead consumers to "incorrectly" perceive products containing MDM so negatively that they cannot be marketed profitably. These assumptions strike at the heart of the MDM controversy. They are critical to Bullock and Ward's analysis, but no evidence of their validity is offered.[1]

The essence of Bullock and Ward's argument (made even more explicitly in their Oklahoma Agricultural Experiment Station research report) is that if consumers are not informed of the presence of MDM, processors could sell an additional S_oS_m units of meat at price P_3 (Bullock and Ward, "Comment," fig. 1). Yet Bullock and Ward also acknowledge that if consumers are made aware of the presence of MDM by current labeling requirements, consumers will no longer be willing to pay a price sufficient to bring forth this additional production. Demand curve *DD′* no longer reflects consumers' willingness to pay. Despite this, Bullock and Ward proceed to calculate the welfare loss from the foregone production using demand curve *DD′*. This error is compounded by the fact that in Bullock and Ward's calculations, the prices (P_3 in fig. 1) and elasticities used in valuing the foregone production are for table cuts and processed meats combined.[2] This leads to further overstatement of the value of the additional production since MDM will be marketed only in processed meat products which will sell at significantly lower prices than those used by Bullock and Ward.

Because their analysis is not focused on the rele-

Douglas W. McNiel is an assistant professor, Department of Economics, University of Central Florida, Orlando.

[1] The American Meat Institute has been collecting information on consumer reaction to the existing labels that seems to support the second assumption.

[2] In the Oklahoma Agricultural Experiment Station research report, Bullock and Ward calculate the potential economic value to society from mechanical deboning of beef as follows: the cost of producing mechanically deboned beef is 40¢ per pound; without the present labeling requirements, producers would be able to market the mechanically deboned beef for $2.23 per pound (the annual average retail price for beef); therefore, the loss to society is $1.83 per pound of foregone production. A similar argument is made for mechanically deboned pork.

vant market and does not address the issue of consumers' willingness to pay, Bullock and Ward do not provide a valid methodology for measuring the welfare effects of MDM labeling requirements. Consumer groups might use their calculations (Bullock and Ward) as a measure of the potential ripoff of consumers if the labeling requirements are changed. These calculations also might be interpreted as the maximum amount meat processors should be willing to spend (for consulting studies, legal services, political contributions, etc.) to alter the present regulatory regime or for marketing programs to convince consumers that MDM is not an undesirable ingredient.

A Demand-Side Methodology

While Bullock and Ward's analysis is inappropriate, their argument that all social costs of regulating MDM are attributable to the labeling requirements may be correct. Whether the labeling requirements result in welfare losses or gains depends upon whether these labels lead consumers to commit errors of omission or errors of commission and the size of any such errors relative to the size of the potential increase in the supply of processed meats.[3]

An error of commission occurs when consumers erroneously overestimate the quality and/or safety of a good. In figure 1, let *d'd'* represent the "correct" demand curve for processed meats containing MDM when consumers have full information (at least partially conveyed by distinguishing labels). Without labeling information regarding the presence of MDM, the "incorrect" consumer demand curve would be *dd*. Uninformed consumers would buy *oq* units at price *p*. Informed consumers would purchase only *oq'* units at this price. Under these circumstances, the labeling requirements prevent consumers from incurring a welfare loss represented by area *efg*—the excess of the additional amount consumers would spend (*q'efq*) over the amount of additional benefit they would receive (*q'egq*). This is the analytical basis of the argument advanced by the consumer groups who have raised the question of MDM use leading to economic adulteration. To ensure against this possibility, consumer groups have gone to court and lobbied extensively to obtain the current labeling requirements.

An error of omission occurs when consumers buy less than they would with full knowledge. Meat processors and their trade associations argue that this is a more accurate characterization of the present situation. Referring again to figure 1, let *dd* now represent the "correct" demand for processed meats containing MDM when consumers have full

[3] These terms apparently were coined by Douglas F. Greer in explaining the theoretical and empirical work of Darby and Karni, Peltzman, and McGuire, Nelson, and Spavins.

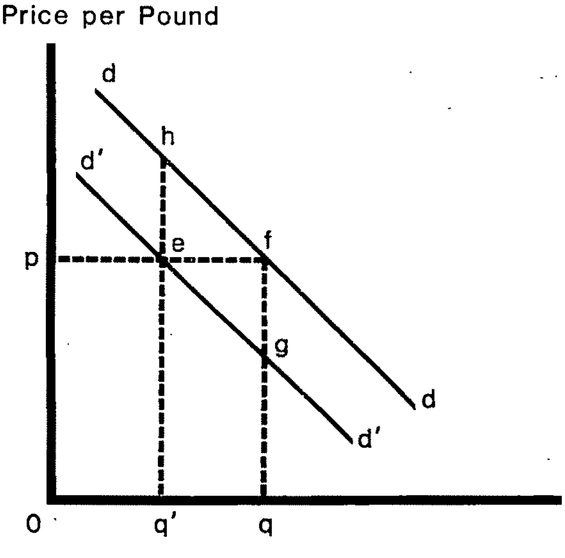

Figure 1. Welfare effects of labeling requirements

information. If the prescribed labeling requirements mislead consumers to undervalue products containing MDM *d'd'* now represents consumers' actual but "incorrect" demand curve. While consumers ought to purchase quantity *oq* at price *p*, because of misinformation (created by, or at least not corrected by, the required product labels) they purchase only quantity *oq'* at this price. Correction of this error would cost consumers an additional *q'efq*, but the added benefit would be *q'hfq*. The difference, area *efh*, represents the net gain to consumers from correcting this error. Correction might be achieved by eliminating the misleading information from the required labels or through information programs to convince consumers that the negative perceptions created by existing labels are unfounded.

Methodologically, if there is a social cost associated with the labeling requirements interfering with consumer sovereignty, it must be analyzed from the viewpoint that the required labels mislead consumers or cause them to behave differently than if they had perfect information about MDM (including its comparative nutritional value and any health and safety risks associated with its use). Consumer groups argue that the present labels provide the information necessary for consumers to express their preferences in the market. If this is true and, on the basis of this information, consumers elect not to buy products containing MDM, then there is no social cost associated with the labeling requirements. Valuing the additional pounds of MDM at a price consumers have demonstrated an unwillingness to pay violates one of the fundamental tenets of applied welfare analysis (Harberger).

Acceptance of Bullock and Ward's argument that the labeling requirements are currently responsible for all social costs of MDM regulation necessitates acceptance of the two assumptions mentioned in the previous section. In this case, p (figure 1) represents the equilibrium price at which products containing MDM would be sold when consumers have full information, and the size of the error of omission caused by the misleading labels, $q'q$, is equal to the potential increase in supply (S_oS_m in Bullock and Ward's fig. 1).

Even if the two assumptions are accepted, the appropriate retail prices and demand elasticities for valuing the increased potential production are not those applying to the entire beef or pork market, but rather those applying only to the processed meat products segment of these markets where at least some semblance of product homogeneity can be assumed after MDM is added. Until the demand-side effects of the labeling requirements are estimated empirically and analyzed in conjunction with the supply-side effects, Bullock and Ward's argument cannot be accepted.

Supply Shifts

Returning to the supply side constraints, there are at least two fallacies in Bullock and Ward's attempt to demonstrate that the 20% use limitation on MDM cannot be constraining.[4] First, the 600-pound carcass in the example will only yield about 444 pounds of salable retail meat (table and processed). Utilization of the mechanical deboning technology does not affect carcass weight, but rather allows meat processors to recover additional pounds of salable retail meat from the same carcass weight. Applying the rest of Bullock and Ward's assumptions yields a 3.6% potential increase in the retail supply of beef and a potential increase in the supply of processed beef of 17.56%. Second, the figure quoted on the ground beef share of the processed beef market (57%) is also for the carcass weight level, not the retail consumption level. This share was computed on the basis of certain assumptions from the production side about the disposition of various types of carcasses—not on the basis of consumption data. These assumptions and the conversion factors used result in this figure understating the share of ground beef at retail. Consumption surveys indicate that ground beef may account for as much as 80% of the processed beef market as defined in my work. When both of these modifications are made to Bullock and Ward's example, the potential increase in the retail supply of processed beef becomes almost 33%, which means that the 20%-use limitation may be constraining. Similar fallacies exist in Bullock and Ward's calculations to show that the 20%-use limitation cannot be constraining for mechanically deboned pork.

Livestock Prices

The impact of the mechanical deboning technology on the derived demand for livestock, an input used in the joint production of many different edible and inedible products, is an area where further analysis is warranted. In equation (1), Bullock and Ward examine this impact. This equation is meant to reflect the net change in incremental revenues and costs of all meat processors when mechanical deboning is adopted widely. This equation measures the change in economic welfare of meat processors only if supply is assumed to be perfectly inelastic. Bullock and Ward's initial interpretation of the equation is that "depending on the value of ΔW, the introduction of MDM technology may result in a welfare transfer from producers to consumers." In the final paragraph they conclude that "if $|\eta| > 1$ as most published estimates indicate, the widespread use of MDM technology will result in some amount of welfare transfer from producers to consumers."

The transfer of welfare from processors to consumers, area P_1ACP_3 in Bullock and Ward's figure 1, was never in doubt. The question is whether processors are net gainers or losers (i.e., the size of area P_1ACP_3, which is a transfer from processors to consumers, in relation to area $BCHE$, which is the gain to producers from reallocating livestock inputs from lower-valued inedible uses to higher-valued edible uses). Clearly, if $|\eta| > 1$, $|P_1ACP_3| > |BCS_oS_m| > |BCHE|$, and therefore, the net receipts of processors will fall implying a reduction in the derived demand for livestock.

Unfortunately, this analysis is likely to give misleading results because of its level of aggregation. The first term in equation (1) probably overstates the revenue loss to producers because the price change is applied not only to the incremental units of production, but across the entire meat market. In practice, use of MDM is unlikely to affect significantly the prices of table meats or even processed meats in which it is not included. To the extent that the processors are successful in segmenting their markets and limiting lower prices primarily to the new products produced with MDM, the technology is likely to increase processors' net revenues and lead to an increase in the derived demand for livestock.

[*Received May 1981.*]

[4] The degree of constraint imposed by the 20% use limitation is overstated in table 4 (McNiel). Rather than indicating a 70%–80% difference from the changes in prices, quantities, and economic welfare associated with free market use of MDM, this regulation should be associated with differences of roughly 30%.

Economic Trade-Offs and the North Carolina Shrimp Fishery: Comment

Ronald N. Johnson

In a recent *Journal* article, Waters, Easley, and Danielson (WED) offered calculations purporting to show the economic trade-offs of fishery regulation designed to reduce the discard of juvenile pink shrimp caught incidentally by fishermen harvesting brown shrimp. Reducing the cull of juvenile pink shrimp by seasonal closure or prohibiting night shrimping implies that the mature pink shrimp catch will be augmented later in the season. WED argue that such regulations would reduce the brown shrimp harvest. Consequently, an economic trade-off arises. Although WED conclude that the incidental catch and discard problem are not severe enough at this time to warrant new regulations to protect juvenile pink shrimp, they have ignored both the common property aspects of the fishery and the response of fishing effort to the potential increase in yields.

Following the model of Gordon and Scott (1955), assume that the total cost of fishing is a linear function of fishing effort. Further assume, as do WED (p. 126), that the demand for shrimp harvested in North Carolina waters is perfectly elastic. For shrimp, the revenue/yield curve can be assumed concave in the relevant range, with a positive first derivative. Under common property access, the Gordon and Scott model predicts that entry will take place until all rents are dissipated; that is, average revenue per unit of fishing effort will equal average cost. If the yield of pink shrimp were increased by allowing more juveniles to reach maturity, the revenue/yield function would shift upward and effort would increase. Once again, total revenue would equal total costs. The economic benefits from enhancement of the pink shrimp fishery via regulation are, in this case, equal to zero. However, in the WED formulation the calculated gross benefits to the pink shrimp fishery are positive. The reason for this is that they treated effort as exogenous. WED's equation (9) (p. 126) assumes no adjustment of fishing effort as yield increases. They essentially ignored the common property aspects of the fishery by not incorporating an effort response function into their model.

Ronald N. Johnson is assistant professor in the Department of Agricultural Economics and Economics, Montana State University.

In the real world, returns to fishery enhancement may not be zero even in an open access fishery. First, if demand is not perfectly elastic, there will be gains in consumer surplus from a larger net catch. Second, fishermen are not identical, and their supply to the industry is not infinitely elastic. Accordingly, rents may not be totally dissipated in an open-access fishery except for the marginal entrant. Third, there are likely to be lags in response to an enhancement project. Thus, benefits of enhancement may be positive over the short run even when the long-run effort supply function is perfectly elastic. Much recent discussion of fishery regulation concerns the response of effort to changes in property rights and regulations (Scott 1979 and Wilen). Limited entry, gear restrictions, and seasonal closures, for example, affect the amount of effort supplied since each fisherman will adjust at the relevant margins. To ignore supply response by individual fishermen in an open-access fishery, or even a regulated one, implies either that the harvesting costs do not matter and/or that effort is somehow exogenously determined. Estimates of economic trade-offs that ignore fishing effort changes due to regulation are primarily biological measures. They are likely to overstate the economic benefits.

Economic Trade-Offs and the North Carolina Shrimp Fishery: Reply

James R. Waters, J. E. Easley, Jr., and Leon E. Danielson

In his comment in this issue on our recent *Journal* article (Waters, Easley, Danielson), Johnson misses the point. We examine the short-run dynamics involved in potential payoff to new regulations. We did not find sufficient short-run net benefits to warrant a policy; hence, we did not look at the long-run equilibrium question of how to preserve those rents. It makes no sense to pursue a problem that is not there.

The reader can quickly verify this by glancing at table 3 in our original article (p. 129). Presented in that table are thirteen sample observations on the discard rate taken between 1970 and 1975. Only one of these rates even approached our estimated break-even discard rates (rates above break-even would imply positive net benefits). We then conclude that, "it does not appear that the incidental catch and discard phenomenon is severe enough under normal conditions to warrant the adoption of policies designed to protect juvenile pink shrimp."

Had we found potential gains (even in most years) from a discard abatement policy, then the question of rent dissipation through entry to the fishery would have been relevant. However, this was not the case and we did not think it necessary to address the matter in the article.

Johnson's charge that we ignored the common property nature of the fishery is curious, given that the study was largely motivated by this feature. We explicitly state (p. 124): "Communal ownership distorts the choice between present and future income because individual fishermen do not consider foregone future income in their cost calculations." The reason, of course, is that shrimp are subject to capture by any fisherman, not just the ones who might forego earlier catch. That is, they are a common property resource. The basic analysis examines policy-induced trade-offs of income streams over time. The absence of an effort response function in our model in no way suggests the common property problem was ignored; it merely reflects an emphasis on the dynamic aspect of the fishery in the short run.

Projected Replacement Needs for Agricultural Economists: Comment

R. A. Schrimper

In the August 1980 issue of this *Journal*, Schotzko reported that the number of Ph.D.s in agricultural economics required to offset anticipated retirements and deaths would increase during the next decade. This finding is in contrast to recent concerns about "overproduction and overeducation" in the United States, considering the rapid expansion of graduate enrollments in most fields (Cartter, Freeman). Implications of growth in the number of Ph.D.s in agricultural economics during the 1970s were noted by Helmberger. Boddy warned, however, that "the scare talk about the current and prospective general 'Ph.D. glut' is greatly overdrawn. . . . In economics and agricultural economics the prospects are far less discouraging than in most other fields" (p. 724).

The primary purpose of this comment is to note some problems with Schotzko's analysis. A second purpose is to discuss some changes in the characteristics and aggregate number of Ph.D.s granted in agricultural economics in the United States during the last two decades.

Shortcomings in Schotzko's Analysis

One problem with Schotzko's estimates of replacement needs is that only those receiving Ph.D.s after 1950 were taken into account in calculating age distributions. Anyone working in 1975 or after who received a Ph.D. prior to 1951 was not considered in Schotzko's age distribution, table 4 (p. 527). This is probably not important for age distributions in 1985 and later. In 1975, however, some of those who received a Ph.D. prior to 1951 would still have been active professionally, even though more than fifty years of age. This would influence the estimated number of retirements and deaths between 1975 and 1985. Omission of this group is likely to have biased downward Schotzko's estimated replacement needs, at least for the initial part of the period considered.

A second problem with Schotzko's analysis involves calculation of a non-reporting adjustment factor. This factor is defined as the ratio of all U.S. degree recipients for the years 1951–66, inclusive, to U.S. degree holders listed in the 1966 handbook. A question raised by this definition is how data for 1951–54 were handled since U.S. and foreign citizenship was not differentiated for these years, table 2 (p. 526). In correspondence, Schotzko indicated that all degree recipients in 1951–54 were assumed to be U.S. citizens. This assumption is troublesome because for the first couple of years when data permitted a separation by citizenship, nearly 20% of all degree recipients were classified as foreign. Assuming that all degrees were awarded to U.S. citizens for 25% of the years used in estimating the adjustment coefficient undoubtedly results in an upward bias. A lower coefficient value would have affected the age distributions in table 4 nonsymmetrically. The older age categories would have been most affected by this adjustment, causing some upward bias of estimated replacement needs. It is not clear that this error would offset the previous downward bias since their respective magnitudes are not known.

Another issue is the nonsystematic underestimation of total Ph.D. output, table 2. The problem is that the degree recipient list in the May *AJAE* can be quite incomplete. For example, if one considers 1968 degree recipients, it is necessary to consider not only the list in the May 1969 issue but also lists in the August 1969, November 1969, and May 1970 issues to get a full accounting. Even then, several gaps exist.

A more complete tabulation of Ph.D. degrees in agricultural economics awarded in 1961–63, 1968–70, and 1975–77 was obtained by the author for another study (Schrimper) by contacting department heads, graduate coordinators, or others at institutions not included in the *AJAE* lists for those years.[1] This data is summarized for those three periods in table 1. The data for 1968 indicates that the number of Ph.D.s was 181, instead of 126 as reported by Schotzko. Similar comparisons for 1969 and 1970 suggest Schotzko's data underestimate total degrees by 25% and 15%, respectively. The downward bias in Schotzko's series appears to be 10% to 20% for 1975–77. These nonsystematic biases would affect Schotzko's age distributions in his table 4. Consequently, the net effect on replacement needs is not obvious.

Schotzko indicates that underreporting in May

R. A. Schrimper is a professor of economics and business at North Carolina State University.

The author is grateful to many colleagues for comments and suggested editorial improvements in earlier drafts of this manuscript.

[1] This compilation was restricted to institutions which usually would have been included in the *AJAE* lists. It does not include some of the top twenty institutions, identified by Spellman and Gabriel, having students between 1940–74 with dissertation interests in agriculture. These were Columbia, New York University, Pennsylvania, MIT, University of Texas, and Yale.

Table 1. Number of Ph.D. Degrees in Agricultural Economics

Time Period and Region[a]	Student Classification: Domestic	Foreign	Total Number of Degrees	Number of Institutions	Average No. of Degrees per Institution per Year
1961–63					
Northeast	23	8	31	4	2.6
North Central	162	57	219	10	7.3
South	50	4	54	7	2.6
West	36	5	41	5	2.7
Total	271	74	345	26	4.4
1968–70					
Northeast	57	33	92[b]	4	7.7
North Central	187	97	285[c]	11	8.6
South	99	17	120[d]	10	4.0
West	53	40	94[c]	7	4.5
Total	396	187	591	32	6.2
1975–77					
Northeast	36	23	59	5	3.9
North Central	113	97	211[c]	11	6.4
South	70	32	102	11	3.1
West	53	54	107	8	4.5
Total	272	206	479	34	4.6

Note: Data for Canadian institutions, Harvard, and South Dakota, which appeared in the *AJAE*, were excluded. The latter two schools each reported one degree during the nine years considered.
[a] Regions were defined consistent with the Census definitions except Delaware and Maryland were included in the Northeast, and Hawaii was included in the West.
[b] Includes two unclassified students.
[c] Includes one unclassified student.
[d] Includes four unclassified students.

issues of the *AJAE* did not seem to be serious based on comparisons with aggregate data of the U.S. Office of Education. Schotzko's numbers, however, are generally lower than values reported by Helmberger, although the two data sets are not directly comparable; one is reported in calendar years and the other in academic years. One problem with Office of Education data is the multiplicity of codes. For example, in some years these data include separate Ph.D. fields in agricultural business, agricultural and farm management, natural resource management, and agricultural economics. Furthermore, the number of agricultural economics degrees recorded by the U.S. Office of Education does not necessarily include economics degrees with agriculturally oriented dissertations granted by some departments regularly listed in the *AJAE*. Use of *AJAE* lists avoids an explicit definition of what agricultural economics encompasses. The procedure implicitly reflects whatever concept individual departments use to identify degree recipients for the *AJAE*.

Changes in Total Degrees over Time

The more complete tabulation indicates the same secular pattern of change as Schotzko's data. That is, output increased from an average of 115 per year in the early 1960s to just under 200 per year in the late 1960s. Then it declined to about 160 per year during 1975–77 (table 1).

The output peak probably occurred shortly after 1968–70, according to Schotzko's data. The total number of Ph.D.s apparently exceeded 200 per year a couple of times during the early 1970s before declining sharply in the mid-1970s. Thus, after an expansion of over 75% from the early 1960s, total Ph.D. output declined by approximately 20% between 1968–70 and 1975–77.

Despite the decline during the 1970s, the total number of Ph.D.s awarded in 1975–77 was approximately 40% larger than during 1961–63. The sharp decline in the 1970s contrasts with the expansion projected by Helmberger and demonstrates the hazards of extrapolating trends. Adjusting published data to account for nonreporting institutions suggests an average of slightly under 175 Ph.D. degrees per year for 1978 and 1979.[2] Thus, the sharp reduction of the early 70s may have ended.

[2] Estimates of 185 for 1978 and 163 for 1979 assume that the total output of nonreporting institutions changed from 1975–77 by the same proportion as that of reporting institutions.

Changes in Composition of Ph.D. Degrees

Practically all of the increase in total Ph.D.s in agricultural economics between 1961–63 and 1975–77 was foreign students.[3] About the same number of domestic students were receiving Ph.D.s in the late 1970s as in the early 1960s. Foreign students increased from 21% to approximately 43% of Ph.D.s awarded for the years under examination. These proportions are consistent with those of Schotzko. Most of the foreign student increase was from Asia, Central America, and South America.

The number of foreign students increased slightly between 1968–70 and 1975–77 in the presence of an overall decline in total degrees. This increase was substantially below the growth experienced between 1961–63 and 1968–70.

Geographical and Institutional Output Characteristics

Universities in the North Central region continue to account for most of the Ph.D. degrees awarded in agricultural economics, although that region's share has declined from 63% to 44%. Since the early 1960s, the relative shares for the South and West have continually increased. The Northeast share increased substantially between 1961–63 and 1968–70 but then declined slightly between 1968–70 and 1975–77. Some of these changes reflect several new Ph.D. programs initiated during the period. Six institutions without any Ph.D.s during 1961–63 accounted for some degrees in 1968–70. Three additional institutions awarded degrees in 1975–77.[4]

The North Central region continues to award the largest number of Ph.D.s per institution per year. Except in the West, the average number of degrees per program declined between 1968–70 and 1975–77 as a consequence of the decline in total degrees and the expansion in number of institutions offering a Ph.D. Except in the North Central region, the average program size was larger in 1975–77 than in 1961–63.

Despite variation in the total number of degrees granted during the three periods, the set of institutions comprising the ten largest programs has been quite consistent, although individual rankings have fluctuated.[5] Berkeley, Cornell, Illinois, Iowa State, Michigan State, Ohio State, Purdue, and Wisconsin were in this set in each of the three periods. Minnesota was included twice and the following were included once: Davis, Chicago, North Carolina State, Oregon State, and Washington State. The institutions appearing most frequently in the top ten are very similar to those of the 1950s identified by Nichols.

The degree of concentration among institutions within the Ph.D. agricultural economics producing industry has decreased during the last two decades. In 1961–63, the ten largest programs accounted for 70% of all U.S. Ph.D. degrees in agricultural economics. In 1975–77, 55% were awarded by the eleven largest.[6] A similar trend was observed earlier by Nichols and is consistent with changes in general economics reported by Spellman and Gabriel, and Boddy. New Ph.D. programs initiated since the early 1960s accounted for approximately 17% of the total agricultural economics degrees awarded in 1975–77.

All but two of the thirty-five institutions included in table 1 are public institutions. Two private institutions, Chicago and Stanford, accounted for slightly over 4% of the total degrees in 1975–77 compared to 5.5% in 1961–63. This indicates continued dominance of public institutions in granting Ph.D.s in agricultural economics noted earlier by Nichols and Hathaway.

[3] In order to tabulate the number of Ph.D.s granted to domestic and foreign students, prior academic training of each individual was used for classification purposes. Those who had a bachelor's degree from an institution outside the United States were classified as foreign students. A few individuals without bachelor degree information were considered to be foreign students if they received a master's degree outside the United States. This scheme led to a clear classification for all but nine students with missing undergraduate information. These nine individuals were not classified as either foreign or domestic students. As a result of this classification scheme, data in table 1 must be interpreted with caution.

[4] A new program at Utah State reported 4 and 7 graduates in 1978 and 1979, respectively.

[5] More detailed tabulations of data in table 1 for each university and information about sources and migration patterns of Ph.D. students are available in another report (Schrimper).

[6] Illinois and Oregon State tied for tenth spot in 1975–77.

Projected Replacement Needs for Agricultural Economists: Reply

Ralph T. Schotzko

Schrimper's comment suggests that some clarification of procedures is required. Three specific points are mentioned by Schrimper as being problematic. These problem areas are (*a*) exclusion of Ph.D. degree holders who received degrees prior to 1951; (*b*) the assumption regarding foreign recipients of U.S. Ph.D. degrees during 1951–54, inclusive; and, (*c*) the problem of under-reporting in the *AJAE*. Each will be addressed in sequence.

Schrimper's concern about the impact of pre-1951 recipients on the replacement estimates is unfounded. The 1966 *Handbook-Directory* provided the base data. All Ph.D. degree holders listed for whom year of birth information was available were included. The confusion appears to have been caused by the non-reporting inflation factor. The inflation was based on U.S. degree recipients for the period 1951–66, inclusive.

It is recognized that problems exist in using any *Handbook-Directory* for this type of analysis. However, as indicated in the original note, the 1966 *Handbook* appears to contain the largest percentage of U.S. degree recipients among the available alternatives.

In the original note, it was assumed that all Ph.D. degree recipients during the period 1951–54 were U.S. citizens. This assumption affects the size of the nonreporting inflation factor (N_0).

Schrimper argues that ignoring the foregn recipients from 25% of the years included in the inflation factor will cause a significant bias. He argues further for an assumption of 22% foreign recipients during the 1951–54.

Ralph T. Schotzko is an extension economist with the Cooperative Extension Service, Washington State University.

Changing the assumption about foreign recipients during 1951–54 affects both the numerator and the denominator of the inflation factor. The inflation factor will increase, decrease, or remain the same depending on the relative changes in the numerator and denominator.

Recalculating N_o assuming 25% foreign recipients during the period 1951–54, and, that they are listed in the 1966 *Handbook* in the same proportion as foreign recipients during 1955–66, changes the value of N_o from 1.37 to 1.34. The effect of this bias is shown in table 1, columns 1 and 4. Column 1 contains the attrition levels presented in table 4 of the original note. Column 4 of table 1 shows the effects of changing N_o from 1.37 to 1.34 and applying it to the original data. The new value of N_o reduces the number of vacancies caused by attrition by nine over the 15-year period. All of the reduction occurs during the 1980s, an average of less than one per year.

Schrimper's third point is valid for two reasons. During the late 1960s, degree recipients were listed throughout the year, not just in the May issues of *AJAE*. The degree recipients listed in the "off" issues were not included in the original note.

Columns 2 and 5 in table 1 contain the estimated attrition levels incorporating the lists of degree recipients from the non-May issues of the *AJAE*. Regardless of the assumption concerning N_o the impact is relatively small. Spreading the difference between either columns 1 and 2 (10 positions) or columns 4 and 5 (3 positions) over fifteen years shows the minor impact of the additional data.

The May listings were checked against *Handbook-Directory* information, wherever possible, to minimize incorrect year of degree informa-

Table 1. Alternate Estimates of Attrition Rates

	Number of Vacated Positions					
	N_o = 1.37			N_o = 1.34		
	Original Data	New Data	20% Adjustment	Original Data	New Data	20% Adjustment
1975–80	250	254	258	250	251	255
1980–85	299	300	307	294	294	300
1985–90	413	418	432	409	411	424
Total	962	972	997	953	956	979

tion. Checks for double listing of recipients were also made.

The problem of nonlisted recipients provides a classic example of the problems inherent with secondary data. No precise measure of the effect of nonlisted recipients is possible. However, by making two assumptions, it is possible to evaluate the sensitivity of the estimation procedure.

Assume: (*a*) that nonlisted recipients during 1967–75 are 20% of the listed recipients (Schrimper's survey indicates this to be a reasonable estimate), and (*b*) that the age distribution of the nonlisted recipients is the same as the listed recipients. The attrition levels in columns 3 and 6 of table 1 are based on these assumptions. Over the fifteen years, the average is less than two additional vacancies per year. However, over half of the increase occurs in the last five years.

In terms of impact, the problem of nonlisted recipients is most important. However, even a 20% increase in recipients increases attrition vacancies by only about 2.5%. The apparent robustness of the estimation procedure indicates that the interval of uncertainty suggested by Schrimper may be fairly narrow.

Perfect Aggregation and Disaggregation of Complementarity Problems: Comment

Antonio Guccione

In a recent article in this *Journal*, Paris proposes new and interesting results on the aggregation of programming models. In particular, he claims to have weakened the perfect consolidation conditions suggested by Day for linear programs and by Oguchi and Guccione for quadratic programs, while retaining their formal framework. His claim is not completely valid. To illustrate, the aggregation of von Thünen's model is briefly considered as an example.

In his classic paper on consolidating linear programs, Day postulates a macromodel that is a complete miniaturization of the corresponding microsystems. The purpose is to construct a smaller model, easier to understand and manipulate than the underlying disaggregate ones. Thus, all the weighting functions relating microvariables (microparameters) and macrovariables (macroparameters) are defined prior to aggregation. In addition, the aggregation weights are economic constants, rather than arbitrary multipliers determined endogenously by the consolidation algorithm. Specifically, the consolidated net revenue vector is restricted to fixed convex combinations of the corresponding disaggregated vectors. This permits all the usual economic interpretations of the weights. That is, on a priori grounds, all microvectors may be equally weighted, some reference to scale introduced, or another economically relevant definition adopted. The resource macrovector is a simple sum of corresponding microvariables. The technological matrix is defined as a convex combination of microtechnologies. Again, the weights are fixed prior to aggregation, allowing a clear interpretation of the macroproblem. The aggregated primal and dual variables are similarly defined.

Consider Paris's claim that Day's aggregation conditions can be relaxed. It is easy to show that the two frameworks are different. In particular, Paris's macrotechnology $\mathbf{A}_0$ is not the same as Day's. Early in Paris's paper, the matrix $\mathbf{A}_0$ is assumed to be a linear combination of the microtechnologies. Later, the matrix of weights, $\mathbf{U}$, is replaced by the non-unique matrix $\mathbf{U}^*$, rendering $\mathbf{A}_0$ a purely formal construct. Because fewer constraints are now imposed on the consolidation algorithm, the solution conditions become less restrictive. If the aggregator $\mathbf{U}$ is not replaced by $\mathbf{U}^*$, and if the elements of $\mathbf{U}$ are properly defined, then the results are not essentially different from Day's.

Since the matrix $\mathbf{A}_0$ is constructed differently in the two approaches, the corresponding macrosystems have different interpretations. In fact, the precise meaning of Paris's macromodel is not always clear. Under some circumstances his algorithm may generate the same weights as Day's. Occasionally, the weights may be interpretable, *ex post,* in some other way. However, they are frequently uninterpretable. Paris (p. 684) tries to rationalize his aggregated technology in terms of "efficiency units," claiming that this interpretation is equivalent to Day's. Unfortunately, the notion of "efficiency units" is ambiguous, and may be meaningless. In any case, an *ex post* interpretation is not, logically, equivalent to an *ex ante* definition.

Similar comments can be made for the aggregation of quadratic programming models. Oguchi and Guccione prove the impossibility of miniaturization. Paris shows that consolidation with variable weights is possible.

The aggregation of von Thünen's model (summarized by Dunn) will illustrate the implications of different assumptions on the weights. Although the analysis is general, consider the location of two agricultural industries on a flat, undifferentiated plain, containing a single market point. These two industries are characterized by (a) fixed prices of the outputs [$p_0^{(1)}$ and $p_0^{(2)}$] and the non-land input (p_2); (b) production functions of the form

$$x_0^{(i)} = x_1^{(i)}/a_1^{(i)} = x_2^{(i)}/a_2^{(i)},\ a_1^{(i)},\ a_2^{(i)} > 0,$$

where $i = 1,2$, $x_0^{(i)}$, $x_1^{(i)}$, $x_2^{(i)}$ are, respectively, output, land, and non-land inputs of industry i; (c) transportation costs defined as

$$p_3^{(i)}\, x_3^{(i)}\, x_0^{(i)},$$

where $i = 1,2$, $p_3^{(i)}$ is the (given) cost of moving one ton of good i one mile, and where $x_3^{(i)}$ is the distance in miles from the market place; and (d) rent maximization. Under these assumptions the first industry will locate within a circle around the market. The second will locate in the complement of a larger circle around the market, provided that

$$[p_0^{(1)} - a_2^{(1)} p_2]/a_1^{(1)} > [p_0^{(2)} - a_2^{(2)} p_2]/a_1^{(2)}$$

$$[p_3^{(1)}/a_1^{(1)}] < [p_3^{(2)}/a_1^{(2)}].$$

Antonio Guccione is a professor of economics at the University of Windsor, Ontario.

He wishes to thank W. J. Gillen and a careful referee for their helpful comments.

It is easy to compute the amount of land utilized and the output produced by each industry.

An aggregate model in which the two industries are collapsed into a single one is obtained as follows. The production function is written as

$$x_0 = x_1/a_1 = x_2/a_2,$$

where

$$a_i = \alpha_i^{(1)} a_i^{(1)} + \alpha_i^{(2)} a_i^{(2)}, \alpha_i^{(1)}, \alpha_i^{(2)} \geq 0, \alpha_i^{(1)} + \alpha_i^{(2)} = 1,$$

and $i = 1,2$. The micro and macro input variables are related by

$$x_i = x_i^{(1)} + x_i^{(2)},$$

where $i = 1,2$. Aggregated output, its price, and its transportation cost are given by

$$x_o = \beta^{(1)} x_0^{(1)} + \beta^{(2)} x_0^{(2)}, \beta^{(1)}, \beta^{(2)} \geq 0,$$

$$p_0 = \gamma^{(1)} p_0^{(1)} + \gamma^{(2)} p_0^{(2)}, \gamma^{(1)}, \gamma^{(2)} \geq 0,$$

$$p_3 = \delta^{(1)} p_3^{(1)} + \delta^{(2)} p_3^{(2)}, \delta^{(1)}, \delta^{(2)} \geq 0.$$

Probably the most natural definitions of these weights are

$$\alpha_i^{(1)} = \alpha_i^{(2)} = 1/2,$$

$$\beta^{(i)} = \bar{p}_0^{(i)} \bar{x}_0/(\bar{p}_0^{(1)} \bar{x}^{(1)} + \bar{p}_0^{(2)} \bar{x}_0^{(2)}),$$

$$\gamma^{(i)} = \bar{p}_0 \bar{x}_0^{(i)}/[\bar{p}_0^{(1)} \bar{x}_0^{(1)} + \bar{p}_0^{(2)} \bar{x}_0^{(2)}],$$

$$\delta^{(i)} = \beta^{(i)} [\bar{x}_0^{(i)}/\bar{x}_0],$$

where in each case $i = 1,2$, and the overbar refers to a base situation. The problem here is to identify conditions under which equal values of the variables x_1 and x_0 can be obtained solving the aggregated model directly or, alternatively, solving first the disaggregated model for $x_1^{(1)}$, $x_1^{(2)}$, $x_0^{(1)}$, $x_0^{(2)}$ and then consolidating them. To test when perfect aggregation of land is possible, consider the conditions under which the following unit rent functions will have the same solution for (maximum) distance from the market:

$$\{[p_0^{(2)} - a_2^{(2)} p_2]/a_1^{(2)}\} - [p_3^{(2)}/a_1^{(2)}] x_3^{(2)} = 0,$$

$$[(p_0 - a_2 p_2)/a_1] - (p_3/a_1) x_3 = 0.$$

Imposing $x_3 = x_3^{(2)}$, rearranging terms, and using the definitions of the macrovariables p_0, p_3, and a_2 produces the following equation:

$$(1) \quad \alpha_2^{(1)} p_2 p_3^{(2)} a_2^{(1)} - [\delta^{(1)} p_3^{(1)} + \delta^{(2)} p_3^{(2)} - \alpha_2^{(2)} p_3^{(2)}] p_2 a_2^{(2)} = [\gamma^{(1)} p_0^{(1)} + \gamma^{(2)} p_0^{(2)}] p_3^{(2)} - [\delta^{(1)} p_3^{(1)} + \delta^{(2)} p_3^{(2)}] p_0^{(2)}.$$

Notice that the variables $p_0^{(1)}$, $p_0^{(2)}$, $p_3^{(1)}$, $p_3^{(2)}$ are exogenous and that the multipliers $\alpha_2^{(1)}$, $\alpha_2^{(2)}$, $\gamma^{(1)}$, $\gamma^{(2)}$, $\delta^{(1)}$, $\delta^{(2)}$ must be treated as fixed for miniaturization. Thus it is impossible to choose values of the coefficients $a_2^{(1)}$ and $a_2^{(2)}$ which satisfy equation (1) for all possible patterns of the exogenous variables. However, land can be perfectly consolidated constraining the exogenous variables to satisfy equation (1). Consider aggregation over outputs. The definition of aggregate output and the production function imply the equation

$$x_1 = \beta^{(1)} [a_1/a_1^{(1)}] x_1^{(1)} + \beta^{(2)} [a_1/a_1^{(2)}] x_1^{(2)}.$$

For perfect aggregation, then, the following relations must be satisfied:

$$(2) \qquad \beta^{(1)} [a_1/a_1^{(1)}] = \beta^{(2)} [a_1/a_1^{(2)}] = 1.$$

In general, equation (2) will not hold because the constants $\beta^{(1)}$ and $\beta^{(2)}$ are exogenous to the consolidation scheme. In summary, miniaturization is possible under constraint for land, but it is impossible for outputs.

Consider, now, free-weights aggregation. Since the choice of values for the weights is open, equation (1) can be satisfied without any restriction on the prices. Similarly, the multipliers $\beta^{(1)}$ and $\beta^{(2)}$ can be selected to make relation (2) hold. However, if the exogenous variables change, the weights must be recomputed. Moreover, the meaning of the aggregates becomes obscure. For example, it is impossible to interpret the variables x_0, p_0, and p_3 in terms of Laspeyres indexes.

In conclusion, as in the case of regression models (see Tintner and Sonderman, and Fisher), we must distinguish between consolidation with fixed weights and consolidation with variable weights. The choice between these approaches depends on the goals pursued by the researcher. Complete interpretability of the aggregate model requires fixed weights. However, if interpretability of some subset of the macroparameters is not wanted, then the corresponding weights may be treated as variables, and aggregation becomes easier. Indeed, there seems to be a trade off between (*ex ante*) interpretability and the stringency of the corresponding consolidation conditions. It is illegitimate, therefore, to compare aggregation requirements which correspond to difference assumptions on the weights.

Perfect Aggregation and Disaggregation of Complementarity Problems: Reply

Quirino Paris

Aggregation is an empirical problem. It arises when a researcher does not wish to or cannot handle the information specifying the microproblem under study. In either case, aggregation entails loss of information. In such circumstances, it seems plausible to search for procedures that minimize this loss.

Although seldom discussed in the literature, disaggregation is intimately related to the aggregation problem. After performing the desired analysis on the aggregate model, often there is the necessity of apportioning the implementation of the preferred macrosolution among distinct microagents.

If it were possible to find a one-to-one relation between the micro- and the macrospaces (the spaces of the disaggregate and consolidated problems, respectively), loss of information would occur neither in the aggregation nor in the disaggregation processes. However, because the microspace is much wider than the macro counterpart, only a portion of the information contained in it can be transferred to the macrospace (via aggregation) and back (via disaggregation). This is the reason for requiring aggregation under constrained consistency. In empirical problems, not all points in the microspace are of interest because they may be, de facto, either irrelevant or inaccessible. Accordingly, a researcher determines, problem by problem, the portion of the microspace that is relevant for his study. Under this careful reduction, it may be possible to establish a one-to-one correspondence between the micro and the macrospace. This is the essence of constrained consistency.

Information is transferred back and forth between the two spaces by means of aggregation and disaggregation operators (matrices). The more general these matrices, the larger the quantity of information that can be preserved in the aggregation and disaggregation processes. Conversely, the simpler the aggregation matrices, the greater the information loss. Matrices composed only by ones and zeros are the simplest aggregation operators, carrying the least amount of information.

A related aspect of the discussion is whether or not the aggregation problem should be "solved" once and for all (with a "solution" reputed valid for any empirical problem), or whether it should be reconsidered each time, in relation to the given empirical problem under study. It seems clear that by opting for Day's approach, Guccione wishes to "solve" the aggregation problem once and for all. Because this goal is very (too) ambitious, he is compelled (as was Day) to admit to consistent aggregation only very simplified and improbable microstructures such as those in which all firms have identical technologies and proportional constraint vectors.

If, on the other hand, a researcher really considers aggregation and disaggregation as empirical problems, he is contented to solve them case by case. Thus, aggregation matrices suitable for one problem will have different structure, numerical components, and meaning in another problem. To me, all this seems perfectly reasonable.

Does this mean that in my approach weights are variable, as repeatedly asserted by Guccione? No. The weights (the aggregation matrices) are fixed for any given empirical problem. In other words, for any set of fixed aggregation and disaggregation matrices as defined in my paper, only those microstructures that satisfy the conditions of the aggregation theorem will admit consistent aggregation. This point is clearly illustrated by the numerical example of tables 1 and 2 in the original paper. Using the same aggregation matrices presented in table 2 and defined a priori (as Guccione claims aggregation ought to be performed), three sets of revenue and constraint vectors (exogenous variables in Guccione's terminology) were selected to show consistent aggregation and disaggregation. Obviously, one could choose an infinite number of such vectors and perform consistent aggregation using the same weights, as long as these vectors satisfy the constrained consistency assumption.

Incidentally, that numerical example illustrates consistent aggregation of a quadratic programming problem. Together with another example specifically developed in the text, it should lay to rest the question raised by Oguchi and Guccione whether or not the dual variables in quadratic programming can be consistently aggregated.

Many assertions are enunciated by Guccione, few of which I can agree with. Most of the points raised in his comment were anticipated in my original paper. Five of Guccione's statements, however, deserve rebuttal. They relate to (*a*) the alleged difference between Day's framework and mine, (*b*) the economic interpretability of weights, (*c*) the interpretability of aggregate quantities, (*d*) the

Quirino Paris is a professor of agricultural economics, University of California, Davis.

definition of aggregate technology, and (*e*) the example of a von Thünen economy.

(*a*) Day's framework is a special case of mine. This much is admitted also by Guccione. Only in this sense are they "different." I prefer to consider my suggestion as a generalization.

(*b*) Guccione limits the economic interpretability of weights to the set of numbers composed by ones and proportions. He refuses to recognize the usefulness of efficiency units. This is surprising. Not only did agricultural statisticians pioneer the use of efficiency units to obtain an aggregate measure of child, male, and female labor; but, more recently, efficiency units have become an important notion for measuring any input subject to technical progress. The alleged ambiguity of efficiency units can be reduced not by eliminating the units, but by their careful definition. They are certainly necessary in the aggregation of nonhomogenous resources.

(*c*) The interpretability of aggregate quantities seems to me more important than the economic interpretability of weights. In this regard, the framework I suggest should be irreproachable because every aggregate relation is defined exclusively in terms of the corresponding microrelations, and no problem of interpretability arises. This point is discussed and illustrated in detail in my paper.

(*d*) According to Guccione, an aggregate technology makes sense only if "defined as a convex combination of microtechnologies." This is clearly unnecessary. In aggregating input-output tables, for example, the consolidated technology is composed of the row and column sums of the microsectors' coefficients. He is also incorrect when writing that the matrix $\mathbf{A}_a$ in my paper is assumed to be a convex combination of microtechnologies. Such a matrix is defined throughout as $\mathbf{A}_a = W'AD$, where W and D are nonnegative aggregation operators. This expression is obviously not a convex combination of $\mathbf{A}$, the microtechnology.

(*e*) The von Thünen example merely indicates the need for aggregation under constrained consistency. Guccione asserts that "if the exogenous variables change, the weights must be recomputed." He then concludes that the weights in my paper are variable. I already pointed out that, in my approach, the aggregation matrices are fixed because one can change the exogenous variables without changing the weights.

Aggregation remains a largely unsolved empirical problem. Knowledge of the most general and flexible mathematical structure by which a researcher can define his model is a prerequisite for progress toward a solution. It is important to suggest that this solution should take into account the implied degrees of freedom problem. In general, it seems convenient to avoid that the specification of aggregation and the choice of weights more than exhaust the degrees of freedom, as in the von Thünen's example of Guccione. In most empirical problems, such a choice is possible under constrained consistency, while preserving the economic interpretability of both weights and aggregate relations. Guccione's comments may be evaluated within this context.

Editor's Note

A correction is necessary in equation (5) on page 304 of the May 1981 issue of the *Journal.* This equation, in the "Reply" written by Mittelhammer and Young, should be as follows:

$$(5)\qquad 0 \le a \le 2\left[\frac{J+\eta}{1+\eta} - 2\right]/(T - K + 2).$$

Also, in the two lines below equation (5) on page 304, X'_{n+1} and X_{n+1} should be x'_{n+1} and x_{n+1}, respectively.

Books Reviewed

Downey, W. David, and John K. Trocke. ***Agribusiness Management.*** **New York: McGraw-Hill Book Co., 1981, x + 459 pp., price unknown.**

The book is written for those interested in an agribusiness career. The authors' stated purpose is to provide a textbook for a 1–3-term undergraduate course. It might also serve as a reference book for agribusiness managers in large and small firms.

The book is organized into five sections, which vary greatly in length and subject matter coverage. Part 1 addresses the role and organization of agriculture. Part 2 deals with financial management and control of the firm. Part 3 is devoted to agribusiness marketing. The next section, only 22 pages, deals with production processes for a firm. Part 5, also short, concerns managing human resources in business. An appendix to the book is designed to help individuals obtain jobs in agribusiness management. Last, the book contains a detailed glossary.

Overall, the book covers a broad subject rather well. However, the coverage of some specific subjects is spotty. For example, the two chapters on management of human resources are thorough and well done, but the chapters on economics touch on many important concepts without explaining why they are important.

Chapter 13 gives scanty coverage to the tools of decision making in marketing. Chapter 14 tells a prospective agribusiness firm employee what the sales profession is like, and Chapter 15 is a thorough description of the selling process.

Instructors whose courses involve economics, accounting, and finance generally find it hard to locate a textbook which fits their needs. Downey and Trocke no doubt will help many such instructors. Other instructors will find some chapters useful as specific references. Still others may find the book an acceptable text after they rearrange the order and coverage of some topics.

The potential value of this book as a reference is mixed. Some material may be too shallow to be of much reference value. Yet, other topics are treated thoroughly. The glossary can be quite helpful for those without recent formal training in this general area. The section on economics may cause problems for those not already well-versed in the subject. The statement, "In a perfectly competitive free market system, profits should not exist" (p. 81), may come as a shock. Moreover, the difference between an accountant's and an economist's view of profits is not well explained.

There are many good points in the way material is handled, and the book is well-written. The writing style is more like an informal conversation than a formal presentation. Each chapter begins with a detailed set of objectives and each is summarized concisely. Each chapter ends with a challenging set of discussion questions and a well-defined case problem. The preface indicates that an instructor's manual is available, but it was not available for this review.

Agricultural extension specialists in agribusiness management certainly should read the book. Sections of the book provide ready-made material for workshops and short courses. No doubt many will find the book a welcome addition to their shelves.

Travis D. Phillips and
G. Wayne Malone
Mississippi State University

Forster, D. Lynn, and Bernard L. Erven. ***Foundations for Managing the Farm Business.*** **Columbus, Ohio: Grid Publishing Co., 1981, xii + 351 pp., $23.00.**

This is a textbook for introductory farm management courses. It is one of several new offerings in the field, after two decades of little innovation. The topics covered in *Foundations for Managing the Farm Business* are typical of other texts currently in print. It offers a bit more material on estate planning (a separate chapter), but a bit less than others on such topics as tax management, strategies for avoiding or managing risks, and miscellaneous records, such as maps and livestock and machinery records.

The strength of the book lies in the richness of detail and example that is provided throughout. The chapter on financial statements, for example, includes an example of each type of statement as it is introduced, followed by a complete set of annual statements for a hypothetical farm. The chapter on budgeting includes not only some examples of partial budgeting, but also eleven separate enterprise budgets for an array of crop and livestock activities. Institutional detail is not neglected, either, with a very nice graph of marginal tax rates for individuals and corporations, tables of federal estate and gift tax rates, and sample contracts for farm-leasing arrangements. The attention to detail is also reflected in the average of fourteen or so questions at the end of each chapter. These questions are relevant to the material and provide a good balance of recall and problem-oriented questions.

The layout of this text is not as refined as those of its competitors, and this detracts from the readability of the book, as does the writing style of the authors. The writing style is occasionally lively and usually straightforward, but generally tends to be laborious.

Treatments of some of the topics are particularly pleasing to this reviewer: the extended treatment of estate management, the frequent application of partial budgeting, and the frequent reference to opportunity costs (especially in evaluating "assets in place"). On the other hand, the treatment of several other topics is not so pleasing. The section on analyzing the farm business describes a number of financial ratios and efficiency ratios, but there is little explanation of how these ratios are to be used in analyzing the business. No standards of performance are offered, and the authors lamely conclude that common sense and good judgment are required to interpret such numbers. The capital budgeting chapter offers not a single comment on the phenomenon of inflation and how to deal with it in evaluating a capital investment decision. It is probably appropriate that the authors emphasize the net present value criterion here, but they offer no comparative evaluation of this criterion with other common criteria such as payback period or internal rate of return. On the question of choosing a discount rate for present value calculations, the authors recommend using the average rate of return on assets, which is an unfortunate departure from their otherwise persistent adherence to the principle of opportunity cost. Finally, the chapter on the difficult subject of labor management strikes this reviewer as being weak. It includes some helpful material on planning the labor calendar, on training, and on learning patterns. But the section on motivation relies heavily on McGregor's Theory X-Theory Y, Maselow's hierarchy of needs, and Herzberg's hygiene-motivational analysis of job satisfaction. Perhaps it is important for students to be aware of these points of view, but it seems doubtful that the material presented is sufficient to improve students' labor management skills. The text could well have included more material on the possibilities of profit-sharing arrangements, on the use of fringe benefits, and on issues in labor-capital substitution.

On balance, this book will certainly be of value to students and teachers of farm management. At $23, it is the most expensive of several available texts. Given its strengths and shortcomings in comparison with other texts, most instructors probably will wish to use it as a reference rather than as the primary text.

Richard K. Perrin
North Carolina State University

Kay, Ronald D. ***Farm Management: Planning, Control and Implementation.*** **New York: McGraw-Hill Book Co., 1981, xiii + 370 pp., $17.95.**

This book, proposed as an introductory farm management text, discusses many traditional areas and emphasizes application of economic principles for analyzing practical problems and the use of budgeting techniques for planning and choosing among alternatives. In contrast to many earlier farm management texts, it places less emphasis on analyzing the details of specific types of farm decisions. The book contains no specialized chapters on crop and livestock management decisions and discusses superficially, if at all, such topics as rotations, soil conservation, livestock replacement decisions, feeding rations, and finishing weights of animals. The book is oriented more to the presentation of fundamental concepts, with less emphasis on rules of thumb and "seat of the pants" philosophy that has characterized many earlier farm management texts. The book has a relatively heavy emphasis on the financial aspects of farm decisions and, like several recent farm management books, contains several chapters traditionally considered to be the province of farm accounting and farm business analysis courses.

The book is organized around three basic functions of management: planning, control, and implementation. Nineteen chapters are divided into five units. Part 1 includes only one chapter and deals with the management function. Part 2 includes five chapters classified together under the title of planning. This section includes the basic concepts of marginal analysis and cost common to recent farm management texts. Coverage of relevant economic notions is relatively complete but the depth of coverage may be insufficient for students with little or no economic background. Instructors may need to supplement these chapters with more illustrations and perhaps supplementary readings. Three chapters of part 2 are devoted to the budgeting processes: enterprise, partial, whole farm, and cash-flow. The sections on crop and livestock enterprise budgets are particularly well done, perhaps the best discussion of this topic available. However, the concept of profit is incorrectly and loosely used as equivalent to net farm income in chapter 5 even though it was properly defined in chapter 4. Whole-farm budgeting is handled in a manner that some will consider a short-cut approach and utilizes the concept of gross margins obtained from enterprise budgets as the basic building block of the farm plan. No suggested planning formats are presented for estimating specific crop and livestock expense, seasonal labor balances, feed production-requirements balances, or machinery cost.

Part 3 addresses the control function of management and includes two financial-oriented chapters dealing with use of balance sheets and income statements and two chapters on farm business analysis and farm records.

Part 4 includes six chapters on the acquisition and management of resources. One chapter discusses the pros and cons of different forms of business organizations, a topic not usually included in farm management texts. The section also includes two financial chapters dealing with credit use and investment analysis. Separate chapters follow on land use, labor management, and machinery manage-

ment. Labor efficiency and farm work simplification are inadequately covered. The discussion of machinery management is well-organized and comprehensive.

Part 5 includes three chapters on miscellaneous topics—income tax management, risk and uncertainty, and professional farm management. The chapter on professional farm management will be useful to some but this space could have been better used to discuss more central issues.

A relatively short farm management text is bound to have some omissions. Little or no mention or discussion deals with farmstead planning, exit and entry processes, marketing alternatives and strategies, environmental concerns, and government programs that impact on farm planning and resource control decisions.

Despite the criticisms above, this is an excellent addition to the available farm management texts and is likely to be widely adopted. The examples, illustrations, and topics considered are not regionally specific. The level of sophistication with respect to basic economics and quantitative tools is modest. The book is unusually well written in a clear, systematic, and concise manner. The narrative proceeds in a logical fashion often following a numbered series of points or issues to be discussed. Each chapter opens with a numbered list of objectives to be pursued and ends with a summary and a set of questions for review and further thought. The reference list and data sets are current and appropriate. This proposed text could be used with a minimum of supplemental readings, a condition of considerable appeal to students. Parts 1 and 2 are essential building blocks for the text. Chapters in other units could easily be reordered or omitted with little or no loss of continuity or understanding.

Lichfield, Nathaniel, and Haim Darin-Drabkin. *Land Policy in Planning*. Boston: George Allen & Unwin, 1980, viii + 321 pp., $39.95.

The main theme of this book is that plans are meant to be implemented and the concern of the authors is to see how the implementation process works and how it might be improved. For the purpose of the book, planning refers to local physical development planning; and it is the British experience that is under scrutiny. Britain is often looked to for its developed planning process, but the reason for its eminence in this area is largely historical accident. A further boost to the planning process in Britain was provided by the need to rebuild large areas of several cities following World War II bomb damage. In their search for better plan implementation, the authors turn for guidance not only to past British experience but to experience in other countries also. One chapter and a substantial appendix are devoted to the latter.

The book divides into three sections, the first of which is largely of an introductory nature and is, I feel, the most disappointing part of the book. In a book such as this, concerned as it is with policy implementation, much underlying theory must be taken as given, with references provided to specific texts. To attempt to deal with such general problems as the economics of market failure in an introductory section does not do the subject justice and, as here, often gives an air of superficiality. This is a pity because the rest of the book is indeed stimulating. The third section comprises just one chapter and presents the authors' ideas on how to reduce the plan-implementation gap and, thus, to improve the implementation process. Section two forms the core of the book.

At the end of the introductory section, the authors conclude that, "planning in a mixed economy has to aim at planned development, which recognises the role of the market but seeks to control it towards social ends" (p. 99). The second section is about how this planned development has been achieved in Britain. Running through the central part of the book is a secondary and fascinating theme concerning the question of equity, or distributional effects, of the various planning policies. Land policy planning has two distinct but not wholly separable components. It seeks to improve allocative efficiency in land use but must be seen to do so in an equitable manner. The inefficiency of unplanned piecemeal development and the effects on land values of various land use policies are served by well-developed theory and may thus be termed international in character. The treatment of the equity effects of what in Britain is termed betterment and in U.S. parlance as windfall and wipeout is, on the other hand, distinctly national and specific to given societies. It seems that such societal views may well be time-specific as well because, as this section of the book shows, British policy at different points in time has viewed these equity effects differently. On the allocative side, the main issues seem to be whether negative planning or planning control is sufficient to guarantee planned development or whether planning authorities need to become involved in a positive

haps the lesson from this section is that this is an area of economic policy where there can be no bipartisan concensus.

Overall, the book is marred by poor production—several quotations are unattributed, printing errors remain, and the footnotes to chapter five appear to be wrongly numbered. The book has a disappointing introductory section but a stimulating central argument, and it is hoped by this reviewer that the former will not detract from the latter the wide readership that it deserves.

Richard R. Barnett,
University of York, England.

Murdock, Steve H., and F. Larry Leistritz. *Energy Development in the Western United States.* New York: Praeger Publishers, 1979, xix + 363 pp., price unknown.

Rising real energy prices during the 1970s, in concert with federal policies to encourage energy independence, greatly accelerated fossil fuel exploration and development in the energy-rich western United States. Not surprisingly, the accompanying rapid infusion of population and development capital into primarily isolated agrarian communities placed severe strains on existing social, economic, and institutional structures. Concern over negative impacts on rural communities, as manifested in an abundance of impact study funds, spawned a great deal of impact assessment research. This book attempts to pull together in one volume some basic observations and generalizations from this growing body of literature. Specifically, the intent of the authors is "to provide an overview of the major dimensions of the social, economic and demographic impacts of energy development on rural areas in the western U.S."

The content and structure of the book, as well as the writing style, suggest a broad audience. The text is readable and should prove useful not only to economists but also to interested social scientists and policy makers. In terms of content, the early chapters of the text (1–3) provide the reader with an introduction to some of the unique physical, historical, and institutional aspects of the rural West which impinge upon community response to energy development. The central chapters (4–9) contain a more detailed discussion of specific effects associated with rapid development, such as demographic changes, alterations in the existing economic base due the imposition of development projects and increased demands on community services. The concluding chapters (10–12) attempt first to integrate the descriptive material from previous chapters into a research framework using examples from fairly comprehensive demographic-economic models and then lead the reader through the myriad of federal and state programs which may provide mitigative assistance to developing communities. A particularly useful feature of each chapter is a short terminal section which presents generalizations for the region drawn from the site-specific data bases and assessment efforts reported in each chapter.

A limitation of most impact assessment work is that the trade-off between meeting short-term informational needs and developing a more general body of knowledge appears to have been decided in favor of specific short-term needs. A strength of this text is that it deals with somewhat broader issues of community development rather than mere data collection and description. By dealing with assessment impacts in this broader context, the authors provide some conceptual rigor to assessment research as well as identification of serious data gaps and problems associated with extending localized study results to entire regions or states.

There are few shortcomings worth noting. The authors cite numerous *ex ante* assessment studies on specific communities to arrive at a range of plausible development effects; yet no *ex post* information (on actual effects) is provided to place the accuracy of these assessments in perspective. An evaluation of the relative predictive ability of some of these specific assessment efforts would allow the reader to judge the value of information provided to decision makers.

In discussing social impacts, the authors point out that such assessments by sociologists are often descriptive at best, with little attempt to impart any form of theoretical structure to the problem area. To a lesser extent, the same appears to be true about the assessment of the effects within the economist's purview. While the authors attempt to provide some suggestions as to an integrating mechanism, the impact assessment area still appears plagued by a lack of formal structure.

Finally, an unavoidable problem associated with any effort of this type is that development is continuing (at perhaps an accelerated pace), compared with the period over which the incorporated analyses were generated. Hence, events and literature that have evolved in the ensuing two years are not included. One would hope, however, that the validity of the generalizations remains intact.

Overall, this book proves to be a useful, descriptive synthesis of the types and magnitudes of community effects being experienced in many parts of the western United States. Indeed the major contribution of this book is to identify common themes from the rather diverse set of site-specific research and assessment studies and thus expand the general level of knowledge on this topic. While the authors readily admit that a complete presentation of impact issues and previous research is beyond the scope of one book, they have succeeded in gleaning a number of important generalizations from the literature which are suggestive of the range of effects as well as future directions for assessment research.

Randall, Alan. ***Resource Economics: An Economic Approach to Natural Resource and Environmental Policy.*** **Columbus, Ohio: Grid Publishing Company, 1981, xiii + 415 pp., price unknown.**

Resource Economics: An Economic Approach to Natural Resource and Environmental Policy is intended as an undergraduate text. It includes much of intermediate microeconomics, welfare economics, exhaustible and renewable resource theory, water economics, and environmental economics. Other topics are covered as well—each of them briefly.

The author's Preface explains much of the way the book was written. "Such courses [in Natural Resource Economics] often attract a diverse group of students" (p. xii). The book is simultaneously pitched to the professional economists and the freshman environmental studies major. One group or the other usually loses out. The freshman will not find the discussion of option value or consumers' surplus helpful, while the senior economics major will find the discussion of the Faustman formula too simple. The discussion of Marshallian and Hicksian demand, I believe, pleases no one. But, there are the (many) parts that are just right for everyone. My favorite was the distinction between compensating and equivalent variation—a difficult concept concisely explained.

The book's philosophical orientation, "If there were no need for resource and environmental policy, there would be no need for applied resource economics" (p. xi), is carried through much of the book. The sections on environmental economics, and particularly the Tellico Dam case study, tie resource economics to environmental policy. The discussion of the Hotelling-Clawson-Knetsch transport cost procedure and the hedonic valuation of air pollution procedure were similarly infused with a (somewhat jaded) practitioner's viewpoint. Randall is clear on what these things can and cannot do.

Disappointing to me were the sections on renewable and exhaustible resources. A scant eighteen pages explain minerals, fish, and forests. All the interesting details—such as the capital theory-traditional fisheries debate, or the redundancy of salmon fishery gear—are lost. The book presents only the capital theory rule for exhaustible resources and does not really explain how such resources enter the analysis. Forestry is described only as an optimization problem; the institutions and their rules of thumb, which are policy, are neither described nor analyzed.

Where the author's contribution is uneven, the publisher's is not. The typeface and layout are so inferior that I would rather read the *Federal Register*.

In summary, *Resource Economics: An Economic Approach to Natural Resource and Environmental Policy* is a long book of uneven quality written to many different audiences.

Peter Berck
University of California, Berkeley

Redman, Barbara J., and John C. Redman. ***Microeconomics: Resource Allocation and Price Theory.*** **Westport, Conn: AVI Publishing Co. 1981, ix + 289 pp. price unknown.**

The authors state in the preface they have "found that many beginning graduate students who either transferred from other fields of study, such as agriculture, mathematics, psychology, sociology, etc., or did not have the opportunity to pursue economics to the level usually expected of beginning graduate students need a beginning course on an intermediate level covering some of the basic principles of economics necessary to analyze problems which are economic in nature. For such courses, we hope that this volume will lessen the burden for both the instructor and the students." Unfortunately, the authors did not achieve their objective.

An intermediate microeconomics textbook should have two characteristics. First, it should cover the material relevant for an intermediate microeconomics course. Second, the discussion should be lucid and provide insights to enhance the readers' understanding of the material. This book receives a passing mark on content. However, it receives a failing mark on lucidity.

Apparently neither the authors nor the publisher took seriously their editing responsibilities. The sixty-six word sentence in the above quote is indicative of the authors' writing style.

Readability is to some extent judgmental. Therefore, the book's entire section on income elasticity is quoted so that prospective readers can make their own judgment about the book's potential as a textbook.

"The level of income has a substantial effect on the amount of a given commodity a person will purchase. The income elasticity (E_i) gives a numerical indication of the responsiveness of a consumer's purchases of a commodity to a change in income. It may be defined as

$$E_i = \frac{\text{relative change in quantity of commodity purchased}}{\text{relative change in income}}$$

or $E_i = dq/q \div dI/I$ which is equivalent to $(dq/dI)(I/q)$. This concept explains how the purchases by a consumer of a given commodity change as income changes with prices remaining constant. The income elasticity can have various positive or negative values. For example, if a 1% increase in income causes a 5% increase in the amount of commodity X purchased, the E_i for commodity X would be a 5; if a 1% increase in income causes a 0.2 or a 0.3% increase in quantity, as is apparently the case of food, the E_i would be 0.2 or 0.3 which means that commodity X is normal since E_i is positive. All income elasticities of normal goods are positive, and income elasticities of inferior goods are negative. A commodity with a negative income elasticity is one for which an increase in income

leads to a decrease in the amount purchased. Some food commodities such as potatoes have a negative income elasticity. If the E_i of demand for a commodity is greater than one, it indicates that an increasing proportion of the consumer's income is spent on the commodity as the income increases. Likewise, if the E_i is less than one, the proportion of income spent on the good falls as income increases. It has been suggested that unitary income elasticity can be considered roughly as the dividing line which separates luxury commodities from those in the necessity category. Under this suggestion, those commodities with income elasticities greater than one would be luxuries and those with income elasticities less than one would be necessities.

"In cases where exactly all of the increase in income is spent on the commodity, the income elasticity is equal to the reciprocal of the proportion of the consumer's income spent on the commodity. Thus,

$$E_i = \frac{1}{kX}$$

where kX refers to the proportion of the income spent on X. This means that if a person is spending 5% (1/20) of his or her income on X and if the person has a 1% increase in income and spends it all on X, he or she will increase the expenditure on X by 20%, thus giving an E_i of 20 for commodity X. If less than all of the increase in income is spent on X, then the $E_i < \frac{1}{kX}$ and vice versa" (p 141).

The final chapter discusses general equilibrium. The reader is more likely to be confused than enlightened by this chapter. In fact, the final paragraph of the book indicates that the authors may have confused themselves on this topic.

"It is beyond the scope of this book on (static) resource allocation and price theory to debate the relative merits of allocative vs. dynamic efficiency if these must be incompatible, especially in the absence of much hard evidence and the abundance of value judgments required concerning the priority of present vs. future generations' consumption, but the importance of dynamic efficiency to static resource allocation cannot be denied" (p. 289).

The book contains the standard microeconomic topics. However, it does have more of an agricultural orientation than most microeconomic textbooks. Unfortunately, this orientation does not overcome the other shortcomings of the book.

J. Bruce Bullock
Oklahoma State University

Thomas-Lycklama à Nijeholt, Geertje. *On the Road for Work: Migratory Workers on the East Coast of the United States,* Series on the Development of Societies, vol. 7. Boston: Martinus Nijhoff Publishing , 1980, xii + 211 pp., $16.00.

The primary objective of the book as stated by the author is to combine "statistical data analysis with descriptive reports on the workers' lives and work" (p. x). The first two chapters and part of the fourth are devoted largely to descriptive reports while the fifth and sixth chapters are the statistical data anlysis. The third chapter describes the political and legislative climate, yet no mention is made anywhere of the extensive CETA 303 programs. The book ends with a conclusions and policy implications chapter. The author closes by noting two conditions which must be met to improve migratory farm workers' future: (*a*) "effective government measures must be implemented to halt the entry of new, economically weak workers into the migratory farm labor stream" (p. 181), and (*b*) strong unions must be created to increase the bargaining power of workers relative to employers (p. 192). The book offers a particular perspective on farm labor, but its lack of balance and sound analysis preclude its usefulness for policy making. Most important, no consideration is given to evaluating trade-offs between various groups affected by policy changes.

The first part of the book dealing with descriptive reports of farm workers freely mixes quotations from published works with the author's own observations on farm workers. Particularly disturbing is the intermingling of reports from the 1930s through the 1970s without discerning changes which have taken place over time. For example, the Department of Labor's Annual Worker Plan is given a great deal of credit for coordinating employment between states, as supported in 1955 and 1959 publications. It is, however, not recognized by the author that during the 1970s, employment arrangements have been coordinated largely outside the formal system with the Annual Worker Plan falling into virtual disuse (Kirschner).

The second section of the book presenting statistical data analysis is seriously lacking in depth. The data utilized in this section were collected in fourteen states under regional project NE-58; greater reliance on original sources would have eliminated unnecessary redundance.[1] In presenting descriptive material, the author chooses to present the raw sample data. A discussion of the more appropriate estimated population characteristics, recognizing the stratified random sampling procedure can be found in many of the original NE-58 publications.

Migratory workers are compared with nonmigratory workers on the basis of estimated earnings relationships for each set. The estimated relations, however, are at best only a description of the two portions of the sample rather than a representation of the respective structures. First, the author examines relationships linear in earnings when it is well documented that the log of earnings is the appropriate specification (Mincer). Also ignored is the extent to which migratory workers have chosen to migrate because their earnings are greater than if they do not migrate, and vice versa, i.e., selectivity bias. Both sexes are included in the same earnings

[1] The author was not associated with that group.

relationships with only a dummy intercept shifter when the common practice is to estimate separate male and female earnings relationships. Finally, no attempt was made to carry out a simple F test for significant differences between the migratory and nonmigratory relations.

The author claims to have found evidence of discrimination. The support is based on the coefficients of the ethnic group dummy variables in the earnings regressions. While it may be true that there is discrimination, the analysis in support of the argument needs a great deal more structure. Not only are the earnings relations not well specified, but no effort was made to draw upon the economic discrimination literature and examine, for example, market discrimination coefficients (Becker).

The final exercise in examining the fourteen-state data was to present no fewer than nineteen two- and three-way classification tables to distinguish migratory from nonmigratory workers. The conclusion is drawn that ethnicity is the determinant factor in migration (p. 157). Rarely are we able to draw such sharp conclusions; one can only wonder why the relatively limited tabular analysis was done rather than a more appropriate multivariate analysis.

If one is looking for an economic analysis of farm workers, it will not be found here. In this reviewer's opinion, the book falls far short of meeting the original objective of combining descriptive reports with statistical data analysis. To truly combine the two approaches would require drawing inferences and observations from the same samples. Not only are these different samples, but the time frame differs considerably in many cases. Moreover, the author's own interspersed observations often deviate considerably from the current farm labor market and conditions.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in the manuscript has not been published, is not being published or considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in the manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of the manuscript gives the AAEA exclusive right to publish, to copyright, and to allow or to deny reproduction of it, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) must explain.
2. **Author's identification.** To protect their anonymity in the review process, authors should not identify themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text. No more than four co-authors will be listed on a published manuscript.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; it is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type all footnotes, double-spaced, on a page following the article. Footnotes should be only explanatory and not for citations or for directing the reader to a particular work. This information can be incorporated into the text.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of a sentence, a parenthetical reference is unnecessary unless page numbers or a date are needed. A style sheet on references and citations is available from the editor.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send three fully legible copies to the editor. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when a manuscript is accepted for publication.
12. **Page charge.** Major support for this *Journal* comes from page charges of $40 per printed page, or fraction thereof, payable by the supporting institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for payment are sent with galley proofs.

American Agricultural Economics Association

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to Sydney C. James, Secretary-Treasurer, American Agricultural Economics Association, Department of Economics, Iowa State University, Ames, Iowa 50011.

Volume 63 Number 5

December 1981 Proceedings Issue

In this Issue: Proceedings from the annual meeting of the American Agricultural Economics Association held 26–29 July 1981 in Clemson, South Carolina

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Ames, Iowa, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, James P. Houck, Department of Agricultural and Applied Economics, 332 Classroom Office Bldg., University of Minnesota, St. Paul, MN 55108

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Ronald A. Schrimper, Department of Economics and Business, P. O. Box 5368, North Carolina State University, Raleigh, NC 27650

Ben C. French

1981 Fellow

Professor, Department of Agricultural Economics, University of California, Davis, 1959 to date; Michigan State University, 1953–58; Vice-chairman/Chairman, 1960–66 and 1976–present.
Vice-president, American Farm Economic Association, 1965–66.
President, Western Agricultural Economics Association, 1970–71.
Editorial Council, *Journal of Farm Economics*, 1962–65.
Research awards: Outstanding Ph.D. thesis, AFEA, 1954; Outstanding Research, AFEA, WFEA, 1957; WAEA, 1957 and 1980.
Consultant: USAID, USDA, Congress of the United States, various agricultural firms.

Ben C. French has made distinguished contributions to the profession in research, teaching, and administration. His standards of excellence are recognized by his students, readers of his research reports, and by the faculty and administrators of his institution.

French was born in California in 1923. His academic work was at Berkeley, where he completed his B.S., M.S., and Ph.D. degrees. He joined the faculty at Michigan State University in 1953, and, in 1959, returned to the University of California-Davis.

His research is noted for its depth and innovativeness. The landmark *Hilgardia* monograph on economic efficiency in plant operations, coauthored with Sammet and Bressler, was developed from his award-winning thesis. The influence of this research on the profession is documented in his excellent review article in *Survey of Agricultural Economics Literature*, volume 1. His research papers reflect a continued interest in efficiency in agricultural marketing in areas such as assembly cost functions (article republished in *Readings in the Economics of Agriculture*), subsector model analysis, and pricing efficiency with long-term contracts. Another focus of research is on applied econometric studies, where his supply response specification for perennial crops has been recognized as particularly innovative. In spite of teaching and administrative duties, his research contributions continue to explore new paths, such as the quantitative analysis of marketing control programs.

Ben French is a dedicated teacher at both the undergraduate and graduate levels. One has but to borrow his lecture notes to see the thoughtful and rigorous development of the subject matter. He has developed new courses and opened areas for research using a systems approach. Ph.D. thesis students, with Ben on the committee, have learned to expect no-holds-barred review comments, good-natured encouragement, and firm guidance. Many of his former students now hold prominent positions in universities, businesses, and government.

Of his twenty-two years at Davis, eleven years have been as chairman or vice-chairman. During these two decades, strong programs have developed at both the graduate and undergraduate levels, due in no small measure to Ben's contributions. His contributions in research, teaching, and service to his university and the profession continue to be substantial.

Philip M. Raup

1981 Fellow

Professor, Department of Agricultural and Applied Economics, University of Minnesota, 1953 to date. Professor, Department of Agricultural Economics, University of Wisconsin, 1949–53.

Member, Editorial Board, *Land Economics,* 1949 to date.

Member, Social Science Research Council Committee on Agricultural Economics, 1961–65; Executive Committee, Agricultural History Society, 1962–63; Committee on Long-Range Land-Use Planning, National Planning Association, 1979 to date.

Member, Board of Directors, American Agricultural Economics Association, 1975–78.

Philip M. Raup has been an effective classroom teacher, an insightful researcher, a student of world agriculture, and a provocative public speaker. He has traveled and lectured widely, served in an advisory role in local, state, and federal governments, contributed broadly to his profession, and collaborated with international agencies.

Phil Raup was born in Kansas in 1914. His education included an A.B. in economics at the University of Kansas, and an M.S. and Ph.D. at the University of Wisconsin. After a year as a research fellow at the Brookings Institution, he entered military service, eventually serving four years in the Office of Military Government for Germany in Berlin. He joined the faculty of the University of Wisconsin in 1949, leaving in 1953 for the University of Minnesota.

Raup has taught courses in land economics, land tenure, and world agricultural development. He has sensitized students to the importance of institutional arrangements, while fascinating them with his broad knowledge of people and facts. He has influenced generations of students, both domestic and foreign, and has taken a keen interest in their later careers.

Professor Raup's catholic interests, broad reading, and sharp intellect make him widely respected in the University community. He often serves on graduate committees in numerous other academic departments. His ability to challenge audiences to think differently,

and thereby to reason, has made him much in demand as a public speaker in the United States as well as other countries. Even when people disagree with him, they still respect the mental refurbishing he caused them to do.

Raup's research over the years has been far-reaching. His quest for facts and flair for detail make him a veritable walking encyclopedia of knowledge on world agriculture. His research has been consistently relevant to contemporary policy issues, and he has a unique talent for searching out data to illuminate a relationship or challenge a widely held belief.

Raup is one of this nation's few scholars of the agriculture in Eastern Europe and the Soviet Union. As a member of a multidisciplinary team, he has visited the same locations in the Soviet Union on a regular basis over a twenty-year period. Among other publications these visits led to, a book, *The Changing Structure of Europe: Economic, Social, and Political Trends,* he coauthored with four of his University of Minnesota colleagues.

For many years Raup had an important influence on land economics work in the United States, particularly the North Central region, where he was an active member of the North Central Land Tenure Research Committee (NCR-6). He also has participated actively with city and state government, the USDA, FAO, the European Commission on Agriculture, and the World Bank.

Raup has had a long and productive career. He has been a prolific writer and public speaker, has demonstrated excellence in many fields of agricultural economics and to world agriculture. He has added to our knowledge in significant ways.

James D. Shaffer

1981 Fellow

Professor, Department of Agricultural Economics, Michigan State University, 1953 to present.
AAEA Award in 1980 for distinguished policy contributions through NC-117, "Organization and Control of the U.S. Food Production and Distribution System."
Consultant to U.S. Department of Agriculture/Economics, Statistics, and Cooperatives Service, 1967–68 and 1980.
Director, Center for Rural Manpower and Public Affairs, Michigan State University, 1974–79.
Chairman of the Michigan Agricultural Marketing and Bargaining Board, 1973 to present.

James D. Shaffer is an intellectual leader and a truly innovative scholar in the agricultural economics profession. Not content with conventional economic theory and its application to contemporary economic problems, he constantly seeks new approaches to the solution of difficult social problems. He has been unusually creative in drawing upon ideas and concepts being developed in several social sciences. Through his extensive writing, teaching, and interaction with other professionals he has stimulated and influenced policies and programs in food system organization and public policy.

Shaffer was raised in Michigan. He received his Ph.D. at Michigan State University and has been a faculty member there since 1949. Shaffer's career has reflected a strong commitment to the missions of the USDA/land grant university system. Early in his career, Shaffer attracted attention for his pioneering work on consumer behavior and demand for food. He worked closely with Dr. Gerald Quackenbush in the development and operation of the MSU Consumer Panel which served as a basis for many publications on food purchasing patterns and the socioeconomic factors underlying the demand for food.

In the 1960s, his research interests shifted toward policy questions in the organization and performance of the U.S. food system. He has become a national leader in developing new approaches to marketing research. His 1968 working paper concerning publicly sup-

G. Edward Schuh

1981–82 President

Professor and Head, Department of Agricultural and Applied Economics, University of Minnesota, 1979 to date.
Professor, Department of Agricultural Economics, Purdue University, 1959–79; and program advisor, Ford Foundation-Brazil, 1966–72.
Director, Center for Public Policy and Public Administration, Purdue University, 1977–78.
Senior Staff Economist, President's Council of Economic Advisors, 1974–75; Deputy Undersecretary for International Affairs and Commodity Programs, USDA, 1978–79.
Award for outstanding Ph.D. thesis, AAEA, 1961; Professor *Honoris Causis,* Federal University of Vicosa, Brazil, 1965; award for outstanding published research, AAEA, 1971; special *Homenagen,* Brazilian Society of Agricultural Economics, 1973; award for best article published in *American Journal of Agricultural Economics,* 1974; award for distinguished contribution to policy, AAEA, 1979.
Director, American Agricultural Economics Association, 1977–80; chairman, Awards Committee for Published Research, 1969–70.
Elected a Fellow, American Academy of Arts and Sciences, 1977.

G. Edward Schuh has been professor and head, Department of Agricultural and Applied Economics, University of Minnesota, since 1979. Previously, he was professor of agricultural economics at Purdue University from 1959–79.

Schuh was born on a vegetable farm outside of Indianapolis, Indiana. He received a B.S. from Purdue University in 1952 and an M.S. in agricultural economics from Michigan State University in 1954. After two years of military service he entered the University of Chicago, receiving an M.A. in economics in 1958 and a Ph.D. in 1961.

Schuh joined the agricultural economics faculty at Purdue University in September 1959. While on the Purdue faculty, he served as visiting professor at the Federal University of Vicosa in Brazil, 1963–65, as program advisor to the Ford Foundation in Brazil, 1966–72, and as first director of the Center for Public Policy and Public Administration, 1977–78. At Purdue he taught graduate level courses in advanced production economics, agricultural policy, applied econometrics, research methodology, welfare economics, and economic development. His research concentrated on supply response, agricultural factor markets, agricultural and trade policy, agricultural development, and rural poverty.

Schuh spent a 1968–69 sabbatical as research fellow at the Development Advisory Service, Harvard University. He was a senior staff economist with the President's Council of Economic Advisors, 1974–75, and Deputy Undersecretary for International Affairs and Commodity Programs, USDA, 1977–78. He has been a consultant to the USDA, to the Ford Foundation in India and Brazil, to the International Agricultural Research Centers, to the Consultative Group for International Agricultural Research, and to other universities and international organizations.

Schuh received the Association's award for Outstanding Doctoral Dissertation in 1961, for Outstanding Published Research in 1971, for Best Journal Article in 1974, and Distinguished Policy Contributions in 1979. He was named Professor *Honoris Causis* at the Federal University of Vicosa in Brazil in 1965 and received a special *Homenagen* from the Brazilian Society for Agricultural Economics in 1973. In 1977, he was elected a Fellow of the American Academy of Arts and Sciences.

General Sessions

Economics and International Relations: A Conceptual Framework

G. Edward Schuh

The world which is rising into existence is still half encumbered by the remains of the world which is waning into decay; and amidst the vast perplexity of human affairs, none can say how much of ancient institutions and former manners will remain, or how much will completely disappear.

Alexis de Tocqueville

Economics has experienced a number of mini-revolutions in the post-World War II period. We have absorbed the revolution of mathematics and quantitative techniques. Capital theory has been transformed as we broadened it to include human capital, with all the new insights this more inclusive concept has provided to the theory of income distribution, trade theory, and the theory of economic development (Schultz 1964, Becker). We have revitalized our insights into the family and the household with the new household economics, rooted in the insights of Becker and Lancaster but going back at least to Margaret Reid. We are constructing a microeconomic base for our macroeconomic theory. We have reincorporated the "political" into political economy. And we finally are beginning to recognize that if economic entities are really as rational as we assume, they create serious problems for policy makers—an idea pointedly brought to our attention by the rational expectations school (Lucas and Sargent).

An important challenge still before us, however, is to understand the emerging world economic system and to devise the institutions that can make it more orderly. The theme of this paper is that within the corpus of economics, we have the conceptual and quantitative tools to understand this complex new world and to design a more orderly, efficient, and equitable international economic system. Moreover given the importance of agriculture in the world economy, it is likely that food and agricultural issues will dominate the international dialogue in the decades ahead. Because of our own proclivity to address applied problems, agricultural economists have important contributions to make in expanding that stock of knowledge.

U.S. foreign policy has been in disarray for at least a decade. Part of this disarray is because our relative political and economic power has clearly declined. At home our domestic institutions either were not designed for today's world, or they are evolving in directions that make it difficult (if not impossible) for us to deal with the world that is emerging. Perhaps uniquely among the democratic countries of the world, our president does not speak for a political party capable of being rallied to provide legislative support for his foreign policy—a phenomenon which baffles other countries. Within the federal bureaucracy there is a proliferation of agencies which play a role in foreign affairs. Moreover, the executive branch no longer makes foreign policy. It is made increasingly by a Congress that may be in opposition to the president, by the public through television and the newspapers, and even by the judiciary, as illustrated by the court challenge to our realignment of policy vis-à-vis mainland China and Taiwan.

There are two maintained hypotheses in this paper. The first is that—contrary to popular belief—the world is not really changing in ways that are beyond our capacity to manage or control. The world only appears to be out of control because we have not generated the knowledge that enables us to understand it and to manage it with wisdom rather than brute

---

Presidential address.

G. Edward Schuh is Head, Department of Agricultural and Applied Economics, University of Minnesota.

Grateful acknowledgement is made for helpful comments on an earlier version of this paper.

political and economic power. The second maintained hypothesis is that many of the problems of international relations are fundamentally problems of economic structure and economic relations. Therefore, the contribution of economists is to assist policy makers in taking a strategic view of the world. However, economists to date have hardly addressed such questions. Equally as important, the issues before us go beyond trade and trade policy—important as those issues may be in their own right.

I will attempt to sketch the elements of a conceptual framework that can serve as a guide in understanding the economic dimension of our international relations and that can serve as a basis for structuring a more rational international economic policy. The intellectual foundation for a strategic conception of the world economy has at least four pillars: (*a*) development theory, especially that variant rooted in the theory of human capital and the new household economics; (*b*) the new institutional economics; (*c*) neoclassical trade theory; and (*d*) the theory of endogenous governmental behavior.

At least two of these provide us with a secular perspective on the evolution of particular economies, their institutions, and the institutions which link them together. The third provides a framework for understanding how an economy such as the United States relates to other national and supranational economies through trade and the international capital markets. The fourth provides a basis for understanding the behavior of governments.

It is worth emphasizing here how little attention economists trained in the neoclassical tradition give to the issues of longer-term growth and intercountry relationships. However, economists and other social scientists from different traditions have long given attention to them. The theory of imperialism rooted in the work of Schumpeter and Baran and Sweezy is an important example, as is the dependency theory of Frank and Cockroft, Frank, and Johnson. Dependency theory has fallen into disrepute as growth rates in many countries of the "Periphery" have outpaced those in the "Center."

Development Theory

The contribution of development theory is the insights it offers to the changes that can be expected in individual economies as they undergo economic development. These insights have to do with changes in the sectoral composition of output of individual countries and, in turn, with the international division of labor. They also have to do with the international distribution of income and patterns of trade likely to emerge.

Economists long have had notions of how the sectoral composition of output for an individual economy should evolve as it develops. List noted that as per capita incomes rise, labor would be transferred from the agricultural to the industrial sector. This tendency is one of the few universal constants one can identify as one looks across the range of countries in the world (Johnston). This simple notion also can be inverted and used as a limited theory of development, with the obvious policy prescription that labor should be removed from the low productivity agricultural sector and transferred to the high productivity industrial sector to obtain eocnomic growth.

Baumol extended this idea to a classic model of stagnation by noting that as development proceeds beyond the industrial state, more and more resources are transferred into the service sector. Since he postulates that productivity growth in the service sector is limited, changes in the sectoral composition of output as growth proceeds lead to stagnation. The critical element in this theory is that labor is both the means and end of production. Examples include the shift of labor from the assembly line to such activities as the performing arts, teaching, and other service activities. All of these typically expand as a country develops. If the demand for such activities should be relatively price inelastic and they should have a positive income elasticity of demand, the composition of the economy will shift toward them as the economy expands, and productivity along with per capita incomes will grow more slowly and ultimately stagnate.

The Baumol perspective is clearly in the tradition of early English economists. It is not pessimistic, however, since equilibrium comes at high per capita income levels. The more recent studies using macrosystem models (Forrester and Meadows et al.) are more directly in the early classical tradition. They point to an equilibrium dependent on increases in the service price of natural resources relative to capital and labor.

Schultz (1974b) suggested a somewhat different theory of equilibrium for the developing

economy that is still consistent with the Baumol perspective. Basing his ideas on Becker's time allocation model and the new household economics, Schultz argues that the ultimate constraint to development is the limit that a twenty-four-hour day puts on the development process. Contrary to Baumol, however, Schultz stands the classical world on its head. The ultimate constraint to development comes from limitations on time for the consumption of household-produced goods and services. This is a constraint within the household not arising from limits on resources or rising costs in production. However, the Schultz equilibrium is also at a high income level. Moreover, this theory is richer since, by including children as consumption goods, it includes a population as well as an income equilibrium.

Nerlove, although obviously in the Schultz tradition, provides a somewhat different perspective. He argues that productivity in the household, where both production and consumption take place, can be raised on a continual basis. Because human capital is one of the main outputs of the household, further investments in human capital actually increase the efficiency with which it can be produced. Hence, there is no reason for an equilibrium level of per capita incomes or population to exist.[1]

The insight that comes from the developmental perspective is that the sectoral composition of output changes as development proceeds. Moreover, the changes occur in response to the rising value of human time, which affects not only the structure of demand but the economic activities that are viable as an economy develops. Increases in per capita income are the essence of economic growth and development. But increases in per capita incomes lead to increases in the wage rate. The latter is significant for production both within the household and in the market place.

With capital accumulation, the industrial sector of an economy can expand relatively easily so long as labor can be released from the agricultural sector at approximately a constant supply price. As this process continues, the wage rate will rise and the country will lose its comparative advantage in labor-intensive manufactured products. The industrial sector will then decline, and the service and high technology sector will expand. Hence, industrialization is not the last stage of economic development; it is only a transition to a high-technology economy.

Of course, the increases in per capita income shift the structure of demand from agricultural output to industrial output to the demand for services and technology-intensive consumption goods. The road for the economy is not completely predictable, however, and one cannot be certain about how the sectoral composition of output will change or what the trade implications will be. U.S. agriculture, for example, has become a high technology industry and an important export sector for the United States.[2] Moreover, if capital can be substituted for labor, industrial activities may remain important as the wage rate rises, as the Japanese have demonstrated with their automobile industry.

These caveats aside, economic development exerts a powerful influence on the sectoral composition of output and on the structure of demand. This has important trade implications and, in turn, important implications for international economic relationships. The structure of demand for raw materials will change as development proceeds, as will the structural composition of aggregate demand.

At present, we find ourselves looking backward and wanting to reindustrialize America. Even granted that there are strategic implications involved, it surely is not in our best interest to turn back to a sectoral output composition that was appropriate for the past. We would be better advised to identify and promote those activities in which we have a comparative advantage. At this juncture, they are high-technology, human capital-intensive industries.

The important point in this context is that the force of economic development, with its associated rising value of human time, drives the economy to a human capital-intensive configuration (Schultz 1974b). Not to capitalize on that configuration is to fail to capture one's comparative advantage.

Another insight from development theory and the theory of human capital deals with

[1] Nerlove's model does predict declining rates of population growth and declining rates of infant mortality, the main features of the demographic transition.

[2] This result is counter to the *dependistas* who argued that the LDCs would be exploited by the advanced countries by virtue of their having to export agricultural products and other raw materials, for which they believed the terms of trade were declining, and importing manufactured products, whose terms of trade they believed were rising. See Prebisch and Singer.

population growth and its quality, both of which are important in a strategic sense. The theory argues that children, especially high-quality children, are time-intensive goods to produce. As per capita incomes rise, there is a strong quality component to the demand for children. This means that quality of children is substituted for quantity as development proceeds. The rising price of time associated with development exerts strong downward pressures on fertility rates. Whether this eventually leads to a population equilibrium or merely a decline in the population growth rate is still an open, and probably empirical, question.

The dynamics of population growth have several other dimensions which the United States will be facing in the next couple of decades. In our case, for example, we can not only expect a low population growth rate, but an aging of the population as well. We may well see a time when a predominant share of our population is elderly. This has important implications for the extent to which we want to depend on a labor-intensive industrial sector or import such goods. It also has important implications for our immigration policy. If we really do need to maintain some labor-intensive sectors for national security reasons, we may be much more willing to accept foreign immigrants in the future.

Finally, the human capital perspective changes the view we take about size of population. Historically, size of population has been an important dimension to the political and economic power countries enjoy on the international scene. But the human capital perspective enjoins us to view labor in both qualitative and quantitative dimensions. Hence, numbers are only part of the story, and probably not the most important. Knowledge and the quality of the labor force become critical. They should receive attention as we assess the strength and power of other countries as well as our own.

The New Institutional Economics

A body of literature has now developed from somewhat diverse sources which attempts to integrate the perspectives offered by the traditional institutional economics and modern neoclassical economics (Hayami and Ruttan, North and Davis, North and Thomas, Schultz 1968). This new perspective is described as the new institutional economics. Contrary to neoclassical economics, disequilbrium is an important characteristic. It argues that institutions and institutional change can be explained by past and present economic forces. This obviously has great import for understanding the development of particular economies and for understanding how individual countries relate to each other.

The institutional economics of John R. Commons was used to explain the evolution of economics and to analyze the effects of institutions on resource allocation and the distribution of income. The evolution of institutions themselves was explained in historical terms, with little room given to economic forces. Much of modern neoclassical economics, on the other hand, pretends that institutions do not exist.

An institution in the present context is a behavioral rule. Our interest, of course, is in those institutions that perform economic functions. These include institutions which govern control over resources and assets (such as private property rights), those that establish the framework for the production and distribution of public goods or services (educational institutions, research organizations, judicial arrangements), and those which prescribe how countries relate to each other economically (trade agreements, for example).

The contribution of the new institutional economics is to help us understand how institutions influence the growth path of individual countries, and how the pace and character of development, in turn, influence those institutions. It provides insights into how international institutions might evolve over time, while showing how those institutions might be better designed. It provides some basis for resolving the North-South debate which currently disturbs relations between the United States and the less developed countries.

One of the primary concerns of this paradigm is to explain nonmarket resource allocation, an important issue. The richness of the new perspective can be seen by the range of problems to which it has provided important insights. For example, Cheung, following Coase, argued that under competitive conditions private contracting between landowner and tenant would lead to the same resource allocation as if there had been competitive factor markets for labor and/or land. This leads to a completely different approach to land tenure arrangements and to property rights in general.

Hayami and Ruttan's work on induced

technical change pointed out how economic forces caused institutional change which then guides technological change onto an efficient growth path. The important insights from this research have generated additional work on efficient institutions and institutional change. (See Binswanger et al., and Ruttan, forthcoming.) Ruttan makes the important point that social scientists should produce institutional innovations in the same way that biological and physical scientists produce technological innovations. Their contribution to expanded income streams for society might be just as great in this role as is the contribution of the biological and physical scientist.

North and Davis, and North and Thomas provide new historical interpretations of the development of the U.S. economy and of the western world as a whole. Institutions and induced institutional change play important roles in these new interpretations. Roumasset specifies an efficiency framework to explain patterns in institutional arrangements found in agricultural production.

The new institutional economics has a number of implications for a strategic conception of the world economy. In the first place, it should make us more sensitive to differences in institutional arrangements among countries, while providing more insight into the rationale for the differences that exist.

Second, understanding the interactions between economic forces and institutions can provide important insights into the particular development trajectory that countries might take. For example, institutional arrangements will determine what share of investment resources are channeled to the formation of human capital and what particular form that human capital will take. Important implications for immigration and trade policy logically follow. Institutional arrangements also determine how externalities (positive or negative) are internalized, with obvious implications for the sectoral composition of output and the proportions in which resources are used. Institutional arrangements will also determine whether the development process is focused onto an efficient or an inefficient growth path.

An especially important class of related problems has to do with the future evolution of the centrally planned economies. Marxian thought may be inverted: centrally planned economics may have the seeds of their own destruction built into the system. The internal contradiction of the centrally planned economies may be rooted in the imperative to invest in human capital as a means to keep up with the more decentralized, industrial countries of the West. Such investments may lead the population of these economies to develop new perspectives on their own institutions. Alternatively, the failure to permit the appropriate institutional changes to take place may condemn the centrally planned economies to a slow-growth trajectory.

The new institutional economics also offers insights into the shape that economic and political unions might take. Economic unions typically occur when gains from trade can be internalized within a partial or complete political unification. Recognition of this explains why economic and political union often goes only so far and then stops.

A superficial look at the Mexican and U.S. economies suggests that there is sufficient resource complementarity to make a case for economic union. Mexico has an abundance of oil and a rapidly growing, young, and unskilled labor force. The United States is short on oil and has a human capital-abundant, aging, and slow-growing population. The disparities in economic and political power make union difficult, however. Insights from the new institutional economics should provide important guidelines as to how to design the institutions that will make economic and political union possible—with enormous strategic implications to the whole world.

A proposition from trade theory offers another example of the potential role of the new institutional economics. The theory of optimal currency areas provides an explanation for why important regions of individual countries have chronically lagged behind other regions. Leff has argued that had northeast Brazil been a separate country with a separate currency, it might well not have lagged behind the rest of Brazil. The same probably applies to the U.S. South and to the south of Italy.

Political pressures can build up in particular regions causing them to break away from the central government. More generally, cases where such exchange rate disparities are likely to arise will be poor candidates for economic and political union. But, armed with the insights of both the theory of optimal currency areas and the new institutional economics, one might be able to design institutional arrangements such as multiple exchange rates that would lead to stable economic and political units.

Other institutional design questions are apparent. In the tradition of Ruttan and the induced innovation hypothesis, what institutions are needed and what support can be found for them to do the research and perform the educational missions pertinent to the international socioeconomic-political system? National intelligence agencies should be doing some of the research on these issues. But to leave such research to the intelligence agencies will be inadequate. Multiple research and education institutions are needed. Moreover, the issues are of national and international interest, not just state or local interest.

A second set of institutional design questions has to do with international economic institutions. The world has become increasingly interdependent. The exchange rate regime has changed, an effective international capital market has emerged, and trade patterns are changing dramatically. All of this is taking place with ever-widening differences in per capita income. Comparative advantage is also shifting rapidly among countries. Such rapid shifts make adjustment more difficult and create political problems.

The end of World War II saw a burst of creativity in new international institutions such as the GATT and the Bretton-Woods conventions. Unfortunately, most were designed by the advanced industrial countries for their own benefit. Moreover, they were predicated, for the most part, on a fixed exchange rate regime.

Today, international political and economic power has changed significantly. The international capital market has grown, while the relative importance of concessional foreign aid and the international migration of labor has declined. The social, economic, and political world is just very different than it was several decades ago.

The southern participants of the North-South debate have been the loudest and most articulate proponents of institutional change in the international community. Yet even in the United States and other industrialized countries there is general dissatisfaction with arrangements for international economic and political intercourse.

The questions here are legion. What institutions are needed to manage the international monetary system? Of what value is GATT when most of the less developed countries (LDCs) are not members despite their growing importance in international trade? How can these other countries be brought in? What institutions can be developed to facilitate trade adjustment and more rapid trade liberalization?

Neoclassical Trade Theory

The neoclassical theory of international trade is not a particularly powerful predictor of trade flows in the complex world of today. However, recent extensions of the theory and growing empirical research enable us to understand trade patterns with greater assurance than even a decade ago.

Despite recent contributions, trade theory is still usually cast in a comparative cost framework. Perhaps the most widely used version is the factor proportions explanation of trade developed by Heckscher, Ohlin, and Samuelson. The standard version of this theory is expressed as a $2\times2\times2$ general equilibrium model. It assumes that production functions are identical across countries and first-order homogenous and that all factors of production can be translated into efficiency units of capital and labor. It assumes that capital is not mobile internationally. It also assumes there are no factor-intensity reversals, and it ignores goods and factor-market distortions. Finally, it is a static theory, and usually assumes "similar" preference structures across countries.

Empirical evidence and common observation question most of these assumptions. In the first place, it has long been recognized that developing countries have large agricultural sectors and trade in primary commodities cannot be explained by endowments of labor and capital alone. Agricultural production requires the services of land in addition to labor and capital. This means that the $2\times2\times2$ model is not very helpful in explaining patterns of agricultural trade. Second, production technology is generally not perfectly mobile across national boundaries, especially in agriculture where technology tends to be location specific. This challenges the common production function assumption.

Third, a rather large and efficient international market for capital has evolved, represented in part by the transnational firms which create so much controversy. Fourth, factor-intensity reversals are fairly common, especially in agriculture (Naya). At low wage-rental ratios agriculture tends to be labor-intensive relative to industry. At high wage-rental ratios, agriculture is capital-inten-

sive relative to industry. For example, agricultural production in the United States tends to be more capital intensive than industrial production, but in Southeast Asia it is more labor-intensive. The existence of different elasticities of substitution in the two sectors is sufficient to ensure that a factor-intensity reversal will occur.

Fifth, goods and factor-market distortions are legion in most countries. Governments intervene in the economy in various ways, often with the specific objective of changing the free play of market forces. Sixth, the extensive risk and uncertainty associated with trade cannot be handled with static models. And finally, Valavanis-Vail demonstrated long ago that demand can reverse a country's trade flows from that predicted by a production-based theory of comparative advantage.

Despite these serious limitations to the standard theory, considerable progress has been made in recent years to extend this framework to provide more realistic and useful models. Considerations of demand and product differentiation have been given increased attention in recent studies (Pagoulatos and Sorenson). The issue of imperfect product markets has been addressed and attempts made to understand trade flows in this broader context (Caves, McCalla, Schmitz and McCalla). Helpman and Razin and Jabara and Thompson have demonstrated that if policy makers are risk-averse, the expected-utility maximizing output bundle is not that produced under free trade, even after correcting for domestic distortions. Instead, expected utility is maximized when domestic prices are distorted away from the international terms of trade by the subjective cost associated with international price uncertainty.

Schmitz and others have extended the simple trade model to account for trade in intermediate goods (Bieri and Schmitz). Jones (1967) has incorporated international capital movements into the theory of tariffs and trade. The literature on the transnational corporation is burgeoning.

Krueger (1977) has examined the possible impact of goods and factor-market distortions on trade patterns. To do this, she found that a meaningful interpretation of the Heckscher-Ohlin-Samuelson model must lie within the manufacturing sector in a world of many commodities and many countries. With this broader perspective, she found that the predictions of the theory were more likely borne out in patterns of specialization within manufacturing than in comparisons of factor proportions in exporting and import-competing industries. Moreover, she found that the relevant endowments were those within manufacturing and not of the entire country.

From our perspective, perhaps the most significant extensions of the theory have been to take account of differences in human capital variables across countries. Kenen's contributions (1965, 1968, 1970) have been especially important in this context, but the work of Keesing (1965, 1966, 1968a, 1968b, 1974) Baldwin, Bharadwaj and Bhagwati, and Stern and Maskus is also important. All show an important role for human capital in explaining trade patterns.

Valentini and Schuh argued that the identical technology assumption of the Heckscher-Ohlin-Samuelson trade model can be salvaged in agriculture with the meta-production function of Hayami and Ruttan in place of the conventional production function. The Hayami-Ruttan framework also provides an explanation for the scarce-factor-saving bias observed in agricultural technology across countries. The Valentini-Schuh model specifies a separable production function as a way of taking account of factor biases in the technology. This is more realistic than Jones' three-factor model, which assumes that each sector uses only two inputs, despite the presence of three inputs in the model. Our statistical tests show that the Hayami-Ruttan human capital variables have a strong influence on trade patterns.

A final dimension to the relationships that trade theory can illuminate is the issue of who gains from trade and what are the sizes of these gains. Considerable controversy still rages over this issue. Neoclassical economists implicitly assume them to be large. Opponents of neoclassical economics and of free trade policy either appeal to dependency theory or unequal exchange (Arghiri). Both imply that one trading partner gains at the expense of another. Proponents of the latter view argue that shifts in the terms of trade show who benefits and who loses from trade. Proponents of the neoclassical view argue that shifts in the terms of trade reflect changes in technology and quality of products. They argue that changes in the terms of trade are generally of less significance than proponents of the opposing view think.

Neither side in this debate has given sufficient attention to the fact that the gains and losses are determined by developments on

both the trade and capital accounts. Brandao has taken a fairly simple trade model and derived the welfare function for an individual country. He finds that whether a country gains or loses from trade is determined not only by the terms on which exports and imports are exchanged, but also by the terms on which capital is exchanged.

The new perspective emerging from modern trade theory can serve as a basis for determining foreign policy and as an important field of economic research. First, our international relations ought to be strongly influenced by the directions of trade and investment flows. Surprisingly, little attention has been given by economists to identifying the locus of comparative advantage and how it might be shifting. U.S. agricultural trade, for example, has shifted strongly toward the centrally planned and LDCs. Yet our international posture hardly reflects this shift, nor does the state of our knowledge about the countries involved.[3]

Within the LDCs, our exports are growing most rapidly to the middle-income countries with rapid growth in per capita incomes. This illustrates the importance of economic development as the source of expanding markets for our exports and emphasizes the important link between economic development and trade.

Similarly, we have done little to evaluate where the marginal productivity of capital might be highest for international investment. Naively, Congress mandated some years ago that our concessional assistance had to be channeled to the poorest of the poor.[4] We abandoned the middle-income countries, many of which were making remarkable progress on the road to economic development. How much economic growth was sacrificed as a consequence of this misguided policy is not known.

The emerging patterns of trade and investment should be a key ingredient in shaping our foreign policy. The key to making such projections is to understand the changing patterns of comparative advantage. The emerging human capital perspective provides a framework for making more realistic projections. It also provides a useful framework for shaping our foreign assistance policy, but except for H. G. Johnson and Schultz, economists have hardly scratched the surface on the economics of foreign aid.

The Theory of Endogenous Governmental Behavior

Most neoclassical economics takes government as a given, treats it as exogenous to the private sector, ignores it, or assumes that it is irrational. Such treatment is a paradox, for the participation of government is pervasive in most economies. The tendency has been for this role to increase over time. Moreover, there is no obvious reason why we should expect governments to be either irrational or unresponsive to economic forces.

Trying to understand the behavior of government is important for three reasons. First, the sheer size of government as a component of economic activities is large in many countries. Second, government is the primary means by which income and wealth are redistributed. The distribution of income and wealth is important to understanding the economics of individual countries.

Finally, government economic policy tends to be pervasive in the economy. A distortion in a relative price will tend to affect all consumers and all producers of the product. Moreover, these effects will spill over from product markets to factor markets, and vice versa. Hence, to ignore government behavior is to leave unexplained a great deal that is important.

Fortunately, a theory or theories of government behavior is (are) emerging that offers considerable promise. Rausser, Lichtenberg, and Lattimore have recently reviewed and synthesized literature which relates to democratic societies. They find that a number of conceptual formulations have been advanced to describe endogenous government behavior. They classify these formulations into four paradigms: (*a*) the liberal-pluralist framework, (*b*) the theory-of-state framework, (*c*) the theory of economic regulation framework, and (*d*) the rent-seeking interest group and conflict resolution framework.

The liberal-pluralist framework is found largely in the public finance literature. There is a large number of variants of this paradigm, but the names of Downs, and Buchanan and Tullock stand out. In general, these models

[3] For a penetrating study of the food and agriculture sectors of the centrally planned economies, see D. Gale Johnson.

[4] In 1975 Congress established "new directions" for U.S. foreign assistance by requiring that the foreign aid agencies give special attention to agricultural productivity, population growth, infant mortality, unemployment, and income distribution. This legislation was well-intentioned. However, it was poorly conceived in concept. For a critique of the agricultural mandate, see Schuh and Thompson.

focus primarily on the policy-setting process and on the relationship between policy makers and voters in particular. Policy relates to societal income distribution. Income alone is considered the indicator of well-being, regardless of source. The effects of voters' interests are described in terms of the distribution of income.

The "theory of the state" paradigm emanates from radical economics (Jessop, O'Connor, and Roemer). Contrary to the liberal-pluralist paradigm, which is based upon a "state" which emerges from an atomistic exchange economy, this paradigm presumes that government institutions emerge from one dominant interest group with significant monopoly power. Moreoever, this formulation focuses upon groups of agents called "classes" rather than individuals. It concentrates on election and legislative choice as well as bureaucratic processes.

The theory of economic regulation owes its origins to Stigler, Posner, and Peltzman. This framework treats government intervention and regulations as normal economic goods subject to the standard economic calculus. Consumers and producers are viewed as demanding government interventions of various kinds, most of which can be interpreted as taxes. The regulators must then seek to balance the marginal political return from an income transfer with the marginal political cost of the associated tax. This paradigm focuses on the election process.

The rent-seeking interest groups and conflict resolution paradigm was partially characterized by Krueger. Zusman and Brock and Magee also have made important contributions. This framework admits both economic and political markets and a process for resolving conflicting goals. Contrary to the economic regulation paradigm, power is not swept under the rug. Instead its formation and effectiveness assume a central role. Moreover, rents are presumed to exist in both economic and political markets. The value of this framework is in the understanding of election and bureaucratic choice processes.

Another important body of literature on government behavior deals with the centrally planned economies, and in particular with the policy cycles that emerge in those countries. It turns out that stagnating growth, which results from increasingly severe distortions, leads to liberalization of policy and faster growth, only to be followed again by growing distortions, stagnating growth, and a repetition of the cycle. (For an example, see Brainard.)

An important contribution of the emerging theory of endogenous government regulation is that it provides insights into how income and wealth are redistributed. Income and wealth are redistributed largely through government intervention. By understanding government behavior we are able to understand some of the forces affecting changes in the distribution of income. This makes for a more complete explanation of the economy.

This research also leads to the concept of efficient distribution.[5] This framework is useful for testing hypotheses about whether government intervention is redistributing income and wealth in an efficient manner. The ability to do this is of obvious importance in understanding whether an economy is on an efficient growth path.

Castle notes the universal nature of the self-interest hypothesis and argues that it applies to the private and public sector alike. He provides possible explanations for why much government behavior appears to be perverse to the skeptical eye of the economist, particularly when such behavior leads to policies which grossly distort efficiency prices in the guise of redistributing income.

Another example of the importance and potential of this perspective can be seen from D. Gale Johnson's study of the centrally planned economies. He finds that the introduction of substantial food price subsidies is an important reason for the rapid growth of agricultural imports by those countries. Understanding these policies is the key to understanding the role these economies will play in international commodity markets in the years ahead. Moreover, it will be the key to knowing the posture the United States should take vis-à-vis food security.

Similarly, the kind and degree of government intervention is important in determining the particular growth path an economy will be on and the rate at which it will grow. This theory provides the means of understanding these issues. This in turn provides a basis for policy vis-à-vis that economy. Ultimately, the theory of government behavior provides the link between politics and economics and

[5] Becker (1980) has provided an important step in providing a formal specification of a model from which tests of hypotheses can be made about the efficiency of income redistributions. For an application of such tests in the context of agricultural commodity markets, see Gardner.

among the three previous pillars of this conceptual framework.

Finally, the theory of endogenous governmental behavior provides a means to understand the planning processes which are important in many countries. Here the questions are legion. One would like to know whether the revealed preferences of public agencies are consistent with the policy objectives stipulated by legislative mandates. Similarly, one would like to know the nature and directions of causation between government structure, behavior, and the how, what, and when of the production of public goods and services.

Key Research Areas

The conceptual framework sketched out above is rudimentary and incomplete. The brief surveys of literature are also incomplete. The four elements of the broader framework are not yet well integrated. However, even in this sketchy outline there are important guidelines for future work which will provide a more adequate analytical framework for understanding the economic dimensions of international relations.

To conclude, it would seem useful to enumerate some of the key research issues which need attention. Among these are the following:

(*a*) The impact of economic growth on the sectoral composition of output.

(*b*) The extent to which knowledge can substitute for natural resource constraints in the process of growth.

(*c*) The impact of investments in human capital on comparative advantage.

(*d*) The relationship between investments in human capital and the optimal level of population.

(*e*) The interactions among economic growth, institutions, and investments in capital of all forms.

(*f*) Institutional designs to facilitate economic intercourse among nation states and to help resolve environmental problems.

(*g*) Identification and measurement of the gains and losses from trade, with separate treatment of commodity markets, capital markets, and services.

(*h*) The behavior of governmental units at all levels, ranging from state trading agencies, through national governments to international agencies.

(*i*) The efficiency of income redistribution policies, at both the national and international levels.

(*j*) The linkages among resource endowments, government policies, institutional change, and the growth path of economies.

The above problems are tractable with our present analytical and quantitative tools. These problems are important to agriculture in particular and to the development of a saner, more productive, and more equitable world economy. Agricultural economists in particular have the tools and instincts for dealing with problems such as these. It is in our grasp to help make this a better world for our compatriots and for humanity as a whole.

Government and Agriculture Revisited: A Review of Two Decades of Change

Dale E. Hathaway

It has now been exactly two decades since I last attempted a comprehensive overview of U.S. food and fiber policy; that review was published as *Government and Agriculture, Economic Policy in a Democratic Society.* Thus, it seems appropriate, as one whose professional life has been spent studying and participating in the policy process, to use this opportunity to examine what has happened in the past two decades and look at where we are headed.

I will focus my review on price and income policy, which I believe is more correctly called commodity policy. I will ignore such important areas as resources use, environment, and rural development for two reasons. One is the obvious lack of space. The other is simply that commodity policy has been and continues to be the core of farm politics, despite the attempts of several secretaries of agriculture to make it otherwise. It is still the basis of the U.S. Department of Agriculture's relationships with the agricultural and agribusiness community.

I will limit my comments to three related issues that have brought great changes to commodity policy; they are (*a*) the restructuring of American agriculture, (*b*) the move to international markets, and (*c*) the changing politics and players in commodity programs.

The period 1961–81 has been one of the most tumultuous in U.S. peacetime history. It opened with the inauguration of the nation's youngest president, who promised to lead the nation toward new frontiers; it closed with the inauguration of the nation's oldest president, who has vowed to return the nation to values and glories of a previous, less complex period. In the area of economic policy, the past two decades saw many of the economic institutions developed in the thirties and forties become inadequate to deal with the tasks for which they were designed, as did many of the economic theories and the policies associated with them. As a result, the nation experienced postwar highs in unemployment and inflation, sometimes simultaneously. The dominance of U.S. economic and political power around the world receded as the "miracles" of growth in Western Europe, Japan, and numerous developing countries occurred throughout the 1960s and 1970s. Although it was not immediately obvious at the time, many of these changes were to have a profound effect on the U.S. food and fiber economy and the related policies that influence it.

Closing the Economic Gap in Agriculture

One of the most important changes to occur in the past two decades has been the economic changes which restructured U.S. agricultural production. Two decades ago substantially more resources were committed to producing food and fiber in the United States than could be justified by the return on investment. On the average the return on these resources in farming was lower than a return to a similar resource investment would have been off the farm; by 1980 this was no longer true. Throughout the 1950s and 1960s per capita income of the farm population ranged from half to two-thirds that of nonfarmers. In 1971 the per capita disposable income of the farm population exceeded 75% of the disposable income of the nonfarm population for the first time in modern history. It has been more than 84% of the nonfarm average in every year except one since 1972, and over 100% in several years. However rough these figures, there can be little doubt that, on the average, the resources producing farm products in the United States have been earning returns comparable to those in nonfarm activities in most years of the last decade. Moreover, if one

takes the inflation-induced capital gains into account, the farm production sector may have enjoyed the largest net gain in real wealth of any major sector in the economy over the past decade.

This is not to suggest that this was true for every producer or for most producers every year. Indeed, quite the contrary was true. Periodically during the 1970s and even now, many producers of some commodities found that they were "trapped" in a position where their cash expenses exceeded their cash incomes, and they were forced to resort to living on inflation-created capital gains or to liquidate their farm businesses. This sense of being economically "trapped" led to large and violent farmer protests in Washington in 1978 and 1979 and the formation of a new agricultural organization, the American Agricultural Movement.

In the 1960s there was widespread belief that the return to resource investment and farm incomes would be intolerably low in the absence of government programs like acreage allotments, marketing quotas, and land retirement programs. The 1970s convinced most producers that these programs could be dismantled and that market forces would produce adequate returns to resources in agriculture for most producers in most years. Thus, the 1970s saw the final dismantling of the network of ineffective production control programs that had been the hallmark of our basic commodity programs since the 1930s. Equally if not more important was a change in perception about government accumulation of commodity stocks. During the 1960s government stockpiling was expected to increase farm income; by the 1970s the farm community was convinced that government stocks depressed prices and income. This change in perception was to alter the policies of government intervention in agricultural commodity markets in a major and probably permanent fashion.

Some observers have suggested that the commodity policies of the 1970s were a continuation of a long trend toward supporting prices at world market levels. I believe that the evolution of policy can be read differently.

Restructuring American Agriculture

In my view, commodity price policy follows rather than leads events in our governmental system. Thus, the changes in policy that have occurred over the past two decades come as a result of changing conditions and not vice versa.

Part of the changes that were to lead to new policies were major changes in the agricultural producing sector. As a result of low returns in agriculture, new entrants in commercial agriculture declined. A decade of sustained growth in nonfarm jobs in the 1960s provided economic opportunities for those who might otherwise have become farmers. The number of workers, both family and hired, employed in agriculture continued to decline during the 1960s at about the same rate as it had in the 1950s.

Over time this process which involved off-farm migration, retirement, off-farm work for some family members, and consolidation and enlargement of farm operations via sales, rental, and new capital infusion produced a commercial agriculture which was far different than existed in 1960. Economies of scale were achieved or exceeded in almost every type of farm in the United States.

The extent of this restructuring is so major that it nearly defies comprehension. In 1960 there were just under 4.0 million farms, with an average net farm income of $2,806. In 1979 there were 2.3 million farms with an average net farm income of $11,526. In 1960, however, farms with an annual sales income of $20,000 provided 48% of all farm products. In 1979 those with sales over $40,000 (a rough adjustment for inflation) provided 82% of all products. In 1960 there was a marked decline in family income from all sources as the volume of farm sales declined. In 1979 the family income is almost flat at $20,000 regardless of sales volume of the farm until the volume of sales is over $40,000 when more resources produce higher average incomes as volume rises.

The massive restructuring of commercial agriculture meant the agricultural labor market was fully integrated with the nonfarm labor market, perhaps for the first time. Simultaneously, an integration of the capital and credit markets also occurred as the modern commercial farms came to depend more and more on outside capital and credit to finance farm enlargement, machinery purchases, and large cash expenditures for annual operation. By the late 1970s the net income from farming had declined to a fifth or less of gross, while in the 1950s it had constituted a third of gross

income. At the same time, commercial farms became extremely sensitive to nonfarm input cost and interest rates.

These changes in the allocation of resources and in the economic situation in commercial agriculture were two significant changes that heralded a shift in the basic U.S. commodity policy. These basic changes in the agricultural economy led to a move away from price supports above market clearing levels and production controls. In the Agricultural Act of 1973 the Republicans finally achieved the market-oriented policies they had sought unsuccessfully throughout the 1950s. They prevailed, however, not because virtue finally triumphed, but because it finally became obvious to most of the farm commodity groups that the old programs had little relevance to their economic well-being.

The Evolution from National to International Markets

The market for farm products two decades ago was relatively slow-growing and stable. In the 1950s the major market for U.S. farm output was at home. By 1960 much of the instability of domestic demand had been removed from the market by income transfer programs that stabilized the demand for food regardless of the business cycle. The foreign markets for U.S. farm products were modest, and mostly the result of U.S. government programs—PL 480, export subsidies, and export credits. Year-to-year changes in export demand brought changes in government stocks, not in domestic farm prices and incomes.

However, during the last two decades the most significant change in demand has come from abroad. In 1960 U.S. agricultural exports totaled only $4.8 billion with a $1 billion surplus in the U.S. agricultural balance of payments, the first such surplus in decades, apart from wartime. By 1980 the level of agricultural exports was over $40 billion with a $20 billion surplus in balance of payments.

The Growth of International Markets

Looking back, it is possible to see that the turning point in the U.S. agricultural export market occurred about two decades ago. It was not until 1957 that the constant dollar value of farm exports exceeded the 1929 level. Therefore, in 1960 there was no strong evidence to suggest that foreign markets would become an increasing factor in the demand for U.S. farm products. In 1950, farm exports produced 9% of cash marketing receipts, in 1970 only 14%, and by 1980 they constituted almost one-third.

The rising export demand that was to change U.S. commodity policy was primarily a result of three factors, although it was influenced by several others. The first was the major growth in world economy outside the United States, led by growth of the Japanese and European economies during the 1960s and early 1970s, followed by some of the high-growth developing countries such as Korea, Brazil, and Taiwan. A second was the population boom in the developing world as medical science lowered death rates more rapidly than birth rates. Concurrently, most developing countries followed policies that failed to invest adequately in agriculture or encourage the adoption of new agricultural technology. Thus, as a group, developing countries shifted from self-sufficiency in food grains to huge net importers of grain in the 1970s. The third factor was the failure of Communist centrally planned agriculture to produce enough food to meet the rising demand for food, especially meats, in their own countries. One by one, the centrally planned economies entered world markets, starting in the mid-1960s and increasing throughout the 1970s. By 1980, these countries together were importing 80 million tons of grains and oilseeds annually, whereas ten years earlier they were not significant importers as a group.

In 1960 world wheat and coarse grain trade totaled 66 million metric tons and the U.S. provided 44%, or 29 million tons. By 1970, world trade in those commodities was 101 million tons, with the U.S. share at 39%. The Russian grain sale of 1972–73 jumped world trade volume in wheat and coarse grains to about 130 million tons, putting the U.S. share at 55%. By 1980, however, the world trade was approaching 200 million tons and the U.S. share was up to 58%.

There also were several ancillary factors which contributed to our rapid export expansion. One was the maintenance of U.S. price supports for grains, oilseeds, and cotton at or below world market levels, a move that began in the mid-1960s and has continued regardless of the political party in power. A second was the devaluation of the dollar and the termina-

tion of the fixed exchange rates which had overvalued the dollar and overpriced our agricultural exports. A third was detente and the ensuing expansion of our trade relations with the Soviet Union and the East Bloc; and finally, the normalization of our diplomatic relations with China.

The confluence of two events, the restructuring of U.S. agriculture and the boom in export markets, was not the result of well-calculated policy, nor was it foreseen by most observers. As a result, the commodity policies of the past decade have been mostly ad hoc attempts to adjust to new economic realities. We are, at the beginning of the 1980s, a long way from achieving a policy which is consistent with the economic and political realities of the world in which we live.

Who Makes Policy: The Congress

While most people recognize that a major change has taken place in the structure of U.S. agriculture and its markets, there is less understanding of the changes this has brought to the politics of agriculture and how the changing face of U.S. politics has in turn related to the substantially different agricultural sector of the 1970s. Indeed, the nonfarm press often implies that little has changed from the days of the old farm bloc.

Washington policy makers in their annual appearance before the venerable Jamie Whitten, chairman of the House Subcommittee on Agricultural Appropriations, tend to think "the more things change, the more they remain the same" as they listen to the chairman tell them how he instructed Secretary Benson to sell farm products abroad at world prices in 1954. But, in reality, there have been profound changes in Congress and the changes have affected the style and substance of farm policy.

First, the average tenure of members of both Houses has declined markedly since 1960. Less than one-third of the forty-seven members of the House Agricultural Committee that wrote the 1977 Farm Bill had ever written such a bill before, and the 1981 bill will be addressed by an equally new group. Part of the congressional turnover is caused by the coattails of the lopsided presidential victories of 1964, 1972, and 1980. Part also is due to the rise of the two-party system in the South, the area that had traditionally dominated the congressional agricultural committees.

Second, committee discipline has disappeared and, despite the current Republican steamroller, there has been no real party discipline in the Congress for a long time on commodity issues. Open government has led to open markup of legislation in committee and in conference, providing the single-issue lobbyist with a field day. The congressional committee process, insofar as the substantive committees on agriculture are concerned, has been dominated by a collection of commodity group representatives primarily concerned with the single or few commodities predominant in their district. One feature that has changed little is the individual commodity focus of the agricultural committees. Observers used to decry the excessive influence of certain commodities in the old farm bloc, but now the focus is more than ever on single commodities. Most thoughtful members are conscious of the trend and privately lament it, but in their public action they have little alternative but to follow the most exorbitant demands of their constituent group.

This could, and sometimes does, lead to blatant excesses and bad policy, dairy and peanut programs being a case in point. The more generous treatment of rice and wheat programs also results from this system.

But, there are two major controls which tend to offset the actions of the agricultural committees and further muddy the policy process. One is the necessity for floor action by the entire chamber. Gone is the day when a committee bill reported by a senior agricultural chairman of the House or Senate was immune from amendment on the floor. Sugar legislation pushed by the sugar and sweetener-producing lobbies met its demise on the House floor in 1974 and again in 1979, and it was the threat of a similar fate that caused the dairy lobby to compromise in 1981.

A second and more powerful check on the substantive committees are the budget committees which were created in the 1970s. These committees have immense power to limit funds that will be required to implement policy. It is in the budget committees that commodity program expenditures must be balanced against social programs, defense, and other national needs. More than any other influence, the congressional budget committees shape national policy, overshadowing both the appropriations committees (which can allocate funds within a sector) and the substantive committees.

Another marked change in the past two decades concerns congressional staff. The congressional Budget Committee has a large professional staff; moreover, each of the substantive committees have sizeable professional staffs. In addition, many individual members now have highly trained professionals on their personal staffs. This explosion of professional congressional staff is a mixed blessing. On one hand, it may reduce the dependence of an individual member on a lobbyist or on the executive branch for information and analysis. On the other hand, it is clear that the congressional staff has all the elements of a bureaucracy including arrogance, lack of responsiveness, and in many cases, a tendency to act as if they were the individual who was elected to make the nation's laws.

However much one may have disliked the old congressional seniority system that existed two decades ago, it is difficult to argue that the present open system which has evolved under the guise of democracy is an improvement. In fact, the new system is a hunting ground for well-financed single-interest groups in all areas, commodity programs, gun control, or social programs, and probably results in less thoughtful and less responsible legislation than that produced by the closed seniority system.

The Executive Branch

Changes in U.S. agricultural markets, the U.S. economy, and the nature of commodity policy have slowly and steadily shifted the decision-making power concerning agriculture within the executive branch. Part of the power shift has occurred within the Department of Agriculture and part between the USDA and other agencies in the executive.

From the 1930s through the 1960s the political power base of the USDA was anchored in the network of state and county committees created under the Agricultural Adjustment Act of 1933 to administer the price support, production adjustment, and agricultural conservation payment (ACP) programs. This organization, first called the Agricultural Adjustment Administration (AAA), then Production and Marketing Administration (PMA), and now Agricultural Stabilization and Conservation Service (ASCS), had its own ties to the commodity groups whose programs it administered and to the congressional farm bloc. Much has been written about its power, its feuds with the farm organizations, and various attempts to bring it under policy control. Traditionally, its administrator answered directly to the secretary of agriculture and to the president.

As its domestic price support and control programs became less significant, the ASCS role in policy began to diminish. In 1969, the Republicans put ASCS under an assistant secretary for international affairs and commodity programs. This effectively moved the policy coordination between domestic and international commodity programs one step away from the Secretary.

More importantly, as international markets for U.S. commercial agriculture became more significant, a major new set of actors outside the USDA entered the agricultural policy process. In the 1950s and 1960s, the USDA had to share policy decisions with the Council of Economic Advisors (CEA) and the Bureau of the Budget because of White House concerns with consumer prices and budget costs.

The expansion in world food trade which surged in the 1970s enlarged the policy-making circle. It rapidly grew to include the State Department, Treasury, the U.S. Trade Representative, and the National Security Council, in addition to the CEA and Office of Management and Budget (OMB). As more agencies, and indeed, cabinet officers became involved in commodity policy decisions, the more these decisions were shifted from the secretary of agriculture to the White House. As some people so unkindly put it, "agricultural policy has become too important to be left to the secretary of agriculture."

This widened participation and shift in the decision-making process created several problems and frustrations that are still unsolved. One is the belief increasingly held by farmers that crucial farm policy decisions are out of the hands of USDA and being made by persons who are unfamiliar with their problems and concerns. In many respects they are correct. Most of the knowledge and analytical capability of the U.S. government regarding world food and agriculture still is in the USDA, and the others involved in commodity policy are either dependent upon USDA analysis or sometimes have little basis for judgment.

It is a curious and somewhat unsettling fact that none of the past four presidents, including the incumbent, have been able to evolve a stable and satisfactory policy process within the executive branch to deal with agricultural

commodity policy. Open warfare between the secretary of agriculture and the secretary of state seems to be a hallmark of Republican administrations. It was no secret that the Democrats had similar, if not as vocally explicit, problems under President Carter. Over the past decades there have been councils, committees, special assistants and other White House attempts to coordinate agricultural commodity policy and make it more rational. None have worked and none probably will.

The inherent reason for the problem is that there is no other department with a major domestic constituency and domestic programs that is also deeply involved in international trade and international affairs. No other sector of the U.S. economy has the economic and political ties to a single department as farmers do to the USDA. No other sector simultaneously sees other departments with quite different interests and constituencies constantly and repeatedly intervening in matters they view as important to their economic well-being.

During the 1950s and 1960s, agricultural policy was made by a tightly knit group that evolved from within USDA. It agreed with, and was highly susceptible to, domestic commodity groups and like-minded congressional committees. Now the participants in agricultural policy decisions appear to come from a sprawling, ill-defined group that seems to be beyond the access of farmers and domestic commodity groups. Increasingly, the secretary of agriculture and his senior policy officials involved in commodity policy have become negotiators and intermediaries between the traditional political forces and the new policy participants. As is the case in all such situations, none of the parties completely trust the intermediaries and all parties blame them for whatever they do not like.

The Agricultural Groups

Two decades ago it was possible to sense that the changes in U.S. agriculture were creating great difficulties for the general farm organizations. As the family farm evolved into more specialized production units, the general farm organizations were not able to bridge the gaps between the specialized economic interests of these production units and provide comprehensive political and economic commodity policies. Nor were they able to offer the intensified, special attention and representation these specialized producers seemed to demand.

As a result, highly specialized groups of producer representatives which represent specific commodity producers (wheat, corn, soybeans, cotton, dairy) have developed. These organizations, which nearly parallel the commodity blocs in Congress, have well-paid Washington representatives who generally are more influential in their specific commodity areas than the general farm organizations are.

In addition to the overall farm organizations and the individual commodity organizations, there are two new groups that have increased in importance and influence on agricultural commodity policy. One is the agricultural cooperators group which was organized as the private sector representatives in the foreign market development activities of the USDA. These cooperator groups, operating with combined producers and USDA funds, have become a major force in international commodity policy on such diverse issues as trade and grain negotiations and export credit. In many ways they have developed the same interlocking political interests with the Foreign Agriculture Service (FAS) that the old commodity groups had with ASCS and its predecessors. And, not surprisingly, controlling FAS has become a problem for the secretary of agriculture, just as controlling the independent policy of ASCS was once a problem.

A second powerful force that has arisen during the past two decades is based in the agribusiness-exporter community. This group represents the interest of private firms and cooperatives whose economic well-being depends upon the rapidly growing agricultural export business. While the most publicity has been given the larger grain exporters, those familiar with the Washington scene know that the specialty-crop cooperatives, cotton exporters, and a handful of rice exporters have exercised immense power on issues of critical importance to their export business. Of course, since ample supplies and moderate prices are good for the export business, these agribusiness groups have added their considerable support, in a quiet way, to policies that maintain moderate price supports, full production, and high export levels.

The rise of the single-interest commodity groups increases the historic problem of achieving coherent, consistent domestic and international commodity policies. Given the

narrow focus of the single-issue commodity groups, there are only two participants in the decision-making process that work toward a balanced commodity policy. They are the general farm organizations and the executive branch of government. Thus, in the 1970s the two traditional antagonists, regardless of administration, the secretary of agriculture and the American Farm Bureau Federation, were more in agreement than in conflict—a marked departure from the general hostility and sometimes open warfare that marked much of the period from the 1930s through the 1960s.

Thus, in the 1970s, on policy matters involving general farm legislation, trade negotiations, and other international agricultural issues the old-line farm organizations acted as an important moderating and countervailing force to the individual commodity groups and narrower economic interests they represent.

Oddly enough, what once was a weakness of the general farm organizations may become their strength in the new policy arena. Many have commented in the past that the general farm organizations' tendency to take positions on broad national and international economic policy issues diluted their effectiveness on commodity policy. But now inflation rates, interest rates, and general trade policy are the base upon which commodity policy rests. Thus, the ability to understand and take positions on all these issues is giving these general organizations a greater influence in commodity policy.

Where We Are Now

Despite some political-philosophical claims to the contrary, the evolution to an international market policy has not been without pain for many agricultural producers and associated industries. This pain has been reflected in their political reaction, and I predict that neither the economic problems nor the political reactions in the agricultural sector have run their course.

Until the 1970s, U.S. agricultural producers had relative price stability for both agricultural inputs and outputs, while demand for U.S. agricultural commodities steadily rose. Now, and over a relatively brief time, all of these stable elements have become uncertain in an agricultural economy highly vulnerable to instability. As we face the decade of the eighties, this instability in demand and price for agricultural inputs as well as commodity prices would appear to be one of the policy issues that must be addressed.

It is useful to remember the sources of that increased instability. Export demand for U.S. commodities is in part a function of world weather, especially in the USSR and a few other major importing countries, as well as in other major exporting countries such as Argentina, Australia, and Canada. Thus, in addition to the instability generated by weather in the United States, the instability of weather and crop yields around the world is also reflected in the demand for U.S. agricultural exports.

Second, the nature of the economies that are increasingly dominating world trade in grains, oilseeds, and cotton also adds to demand instability. The LDCs and the centrally planned economies have accounted for most of the growth in U.S. agricultural exports. Most centrally planned and LDC economies have state-controlled central buying units. In a traditional sense, our growing export markets are not markets at all. Lower or higher commodity prices are not translated into changes in consumer prices, within those importing countries. The decision to import and how much to import is based more on internal political circumstances than on economic market mechanisms. All of these factors add to the instability in the export market.

Finally, in that portion of the world where market mechanisms actually operate, we find tariffs and variable levies applied to agricultural commodity imports to prevent world market prices from affecting internal markets. In the few really open markets that do operate, flexible exchange rates can and do affect import demand in ways and degrees that were not anticipated.

Demand instability is, of course, reflected in unstable commodity prices. Some idea of the impact of this instability can be seen by comparing the year-to-year variations in farm prices and incomes in different periods. The variation in crop prices from 1972–78 was six times that of 1955–63, and four and one-half times that of 1964–71. For farm income, the variation in the 1972–78 period was two and one-half times that in 1955–63, and one and one-half times that of 1964–71. The most stable element in the system has now become nonfarm income of farm people, hardly a consolation to full-time commercial farmers. For

crop producers, the use of target prices has been the first line of defense and protection against the instability of demand. This concept, adopted from a 1930s income payment program, offers some protection against low prices but is both expensive and highly asymmetrical in terms of economic costs and benefits.

Target prices for wheat and feed grains offer no protection to dairy, meat, or poultry producers, or ultimately, to consumers who are subject to sharp export-induced price increases. In order to deal better with the inherent instability facing U.S. agriculture in a world market, the administration implemented and the Congress approved in 1977 a farmer-owned reserve program for wheat and feed grains. Not surprisingly, the individual commodity groups have tried to use the reserve as a price support program rather than a supply-price stabilization program.

For forty years, the U.S. government tried and learned, more or less, how to maintain the price of farm commodities during periods of excess capacity and surpluses. We have had little experience and have not learned how to maintain reasonable price stability that is required both by farm producers and consumers at home and abroad, even though efforts have been made.

When I was a graduate student, *Agriculture in an Unstable Economy* (Schultz) was an important work for both its theory and its policy applications. But for a long period, mostly because of federal commodity programs, instability was a relatively insignificant issue in farm policy.

Now once again instability will be a policy issue in the next decade. On the cost side, commercial agriculture finds itself at the mercy of OPEC, U.S. and world monetary policy, and worldwide industrial price policy for inputs such as steel, fertilizers, and chemicals. On the market side, there is unstable demand, unstable exchange rates, unpredictable U.S. government trade policies and unpredictable foreign government policies regarding imports. In my view, the U.S. agricultural producers are only beginning to understand the nature and extent of this instability and the adverse consequences it can have upon their economic well-being.

Not surprisingly, the debate will focus on the proper role of the federal government in stabilizing commodity prices in the new economic context. But, the debate and policy actions will bring conflicts that are new to commodity policy.

On one hand, the commodity producers who are now feeling the full brunt of the new instability will push for policies that expand demand and maintain high, stable, commodity prices. On the other side will be the broad array of consumer and domestic users whose economic interests are best served by controlling price increases. We have already seen three short-supply embargoes in the past few years; and, for a variety of reasons, they have been the most disruptive policy actions taken by the federal government since the inauguration of commodity policies in the 1930s.

One tends to forget that the old domestic commodity programs evolved into a system whereby nobody was surprised—not farmers, marketers, speculators, or consumers. Moreover, most were involved in the development of the policies. But the new government interventions have surprised everyone, pleased few, and enraged the commodity producers more than any single issue in decades.

A related but somewhat different issue will revolve around the proper role of government in international commodity affairs. In a world where international commodity trade is heavily influenced, if not dominated, by governments, it is patently ridiculous to say that the U.S. government will play no role. The famous Carter grain embargo against Russia in 1980 proved government action in the name of foreign policy can be as disruptive and politically unpalatable as short-supply grain embargoes.

The commodity groups, as expected, want the best of all worlds. On one hand, they want government export credit, government power to increase market access and government action to stop other countries from acting "unfairly" in international markets. At the same time, they lead the crusade to end government "interference" in international markets. Of course, one group's "interference" is another's preferred policy for a number of political and economic reasons.

Because of the new participants in the policy process and the economic and political complexity of the new international issues, I believe there will be more violent and prolonged political battles over the proper role of government in international commodity policy. When one considers the importance and interrelations of the two major issues, domestic price stability and the role of government in

international markets, it is easy to predict that they will not be settled quickly nor easily.

Agricultural Economists and Commodity Policy

The agricultural commodity policies of the 1930s were developed in large part by professional agricultural economists, many of whom have been rightfully honored by this association. In the post-World War II period, however, the majority of professional agricultural economists developed a singular disdain for commodity policy, abandoning it for resource policy and development policy among others. Only a few members of our profession continued to pursue the problems of commodity policy.

As one who has been involved in the confusing and somewhat painful transition to the new international policy, I have been surprised and concerned at how little our profession has to contribute to discussions of the new issues and problems that face the United States.

Ours is a discipline that has espoused the greater use of markets, but it turns out that professionally we appear to understand little about how either domestic or international commodity markets really work. The burgeoning field of international commodity trade is dominated by business school graduates rather than agricultural economists, and some have gone so far as to suggest that training in economics, and especially agricultural economics, is a handicap to understanding commodity markets.

We have spent millions, if not hundreds of millions, of public and private money to build computer models. Few, if any, of these models have a satisfactory international component.

Equally disconcerting is the fact that as a profession we have little access to, and few working relationships with, many of the new actors on the policy scene. The profession's longstanding ties with the USDA are appreciably weaker than in the 1960s; and how often does the State Department, Office of the U.S. Trade Representative, Treasury, Commodity Futures Trading Commission, International Trade Commission, and other major agencies that influence commodity policy turn to the members of our profession for analysis and advice? In my recent experience, not often, and probably for good reason.

It is ironic that at a time when there is a need for a greater understanding of the broad relationships of macroeconomics to agricultural commodity markets, the group which should be well-trained and prepared to deal with such issues is so little used and has little to offer. I would guess that there are more professionals engaged in buying and selling agricultural commodities on world markets than ever before in history, and more professionals developing and analyzing government commodity policy around the world than ever before, and that the proportion of them trained in agricultural economics is the lowest ever.

Again, I have no specific suggestions to reduce the widening gap between what I believe will be the major economic political problems in commodity policy and the professional focus of agricultural economists. I think this gap is not healthy for either good policy or a strong profession.

Agricultural Economics in an Evolutionary Perspective

Kenneth E. Boulding

The search for an evolutionary perspective in economics goes back a long way. I have argued, indeed, that Adam Smith was the first evolutionary economist, that Malthus was the second, and that it was no accident that Darwin got his idea of natural selection when he was reading Malthus one evening "for amusement" (p. 120). The search for an evolutionary perspective is a search for a model which will enable us to perceive structure and pattern in the great ongoing flux of the universe through space and time.

The evolutionary "vision," which is perhaps a better word for it than "model," is a way of looking at an enormously complex universe, rather than an explicit model of a simpler reality. It sees the evolution of the universe as a process of constant ecological interaction under continually changing parameters. At any one moment the universe is a set with a large number of populations of different species. A population is a set of elements which are alike enough to be interesting, though they may not be identical in form and structure. A species is anything which has a population. It may include subatomic particles, photons and electrons, chemical atoms, molecules, DNA and genetic structures, cells, organisms, human beings, ideas, words, commodities, securities, money, and so on. The population of any species grows by additions and declines by subtractions. Additions may come from the formation of elements, from chemical reaction, as when hydrogen combines with oxygen to produce H_2O, from replications as with DNA, from births in the case of organisms, from the growth of seeds and plants, from the learning of know-how or know-what, from the production of human artifacts and goods, and so on. Subtractions come from such things as atomic fission, which destroys elements; the disassociation of chemical compounds; the disintegration or mutation of DNA; the death of organisms; the forgetting of learned structures; the consumption of commodities; and so on.

A population grows if additions exceed subtractions, and declines if subtractions exceed additions. If it declines far enough, it becomes extinct and is reduced to zero. In any one population the additions and subtractions will be functions of all other populations of species around it that constitute its environment. Some of these will have favorable effects and make the population grow; others will have unfavorable effects and make it decline. For any population in a given environment we can postulate that it will have an equilibrium level at which additions equal subtractions and the population neither grows nor declines. If this equilibrium is to be stable, then at a population lower than the equilibrium level, it must increase; above the equilibrium level, it must diminish.

In a given habitat we can postulate an ecological equilibrium in which all interacting populations are in equilibrium. Each population is at a level at which, on the whole, it is neither rising nor falling. An equilibrium population may be called a "niche" in such a system. This is a term used rather loosely by ecologists, but the above definition seems to be most meaningful.

The ecological interaction which creates niches is "selection." It is a very complex process. Darwin's "struggle for existence" is a most unfortunate metaphor. Actually ecological interaction involves very little struggle. Most of it is completely unconscious. There are three major types of such interaction. First, cooperative or symbiotic interaction in which an increase in population A produces an increase in the equilibrium value of population B, and vice versa. There is mutually competitive interaction in which an increase in population A produces a diminution in the equilibrium value of population B, and vice versa.

Invited address.

Kenneth E. Boulding is a distinguished professor of economics emeritus, Institute of Behavioral Science, University of Colorado.

Then there is a mixed relationship characterized, for instance, by predation or parasitism, in which an increase in A, a predator, diminishes the equilibrium population of B, but an increase in the population of B increases the population of A. There are limiting cases here of indifference. Thus, an increase in A might increase or decrease B, but an increase in B may not affect A at all. This happens sometimes when A is a dominant species.

Ecological equilibrium is, of course, a mental construct. It is probably never found in nature, although it is a useful concept because it does interpret the dynamics of ecosystems as they may be approaching an equilibrium. The equilibrium position, however, is a function of the parameters of the system and these parameters are constantly changing. This is mutation. The change may be in physical parameters such as temperature, as when the earth warms up or cools off in a succession of ice ages. There may be changes in material population such as soils and soil components which erode. There may be atmospheric changes following eruptions or the impact of an asteroid—such an impact is supposed to have exterminated the dinosaurs. Then there are genetic changes which create new biological species. A change in a single parameter of an ecological system may change the niches of all populations in it. This is the great ecological principle that everything depends on everything else.

In order to complete the model, two further concepts must be developed. The first is that of the "empty niche"—that is, the population which would have a niche in an ecosystem if it existed. Thus, in the nineteenth century there was clearly an empty niche in Australia both for rabbits and for European-type humans. Once they were introduced, they expanded rapidly into the niche. The filling of an empty niche, however, changes all the existing niches in the system and, indeed, the system of empty niches itself. The introduction of rabbits into Australia probably diminished many populations of indigenous species. It also created an empty niche for the organism which produces myxomatosis, a disease of rabbits. When this was introduced, the niche for rabbits shrank. A constant ecological ballet is going on, therefore, all the time, with empty niches being filled, parameters changing, and the niche structure changing. This is evolution. If there is such a thing as a final ecological equilibrium, it is a very long way off and we know nothing about it. The universe is a disequilibrium system and has been from the very beginning.

The second important concept is that of production, a special form of addition to populations, which rises to prominence with the development of DNA and of life and the distinction which then develops between the genotype and the phenotype, the egg and the chicken. Production is the process by which a genotype is transformed into a phenotype. It is not of great significance in pre-biological evolution of physical and chemical species. The phenomenon of catalysis, the role of which in physical and chemical evolution is still largely unknown, is in some sense a precursor of genetic structure in the sense that the catalyst has a structure which imposes its own patterns on its physical and chemical environment.

With the development of DNA, however, the distinction between the genotype and the phenotype becomes very important. DNA has two remarkable properties: the first is that of self-reproduction (I have sometimes called it "the first three-dimensional xerox machine"); second, its property of "know-how"—that is, its ability to organize the production of a phenotype. We see this in a primitive form in asexual reproduction as each half of a divided cell is able to grow into a complete cell because each half contains the essential genetic information which organizes its growth. We see it spectacularly in sexual reproduction, where a fertilized egg has the capacity of growing into a member of the phenotype species which produced it and hence creates an addition to the species population.

Production, then, is the process by which the genotype becomes the phenotype. It starts off with the genetic factor, which is the "know-how." In order for this know-how to be realized, however, there has to be a sufficient amount of the "limiting factors," which can be classified roughly as energy, materials, space, and time. A fertilized egg must be able to capture energy for at least three purposes: to transport and transform selected materials into the growing organism, to sustain the temperatures at which these transformations can take place, and to convey information which selects the materials. The right materials must also be available. There must be space in which these processes can be carried out. And there must be time for them to be carried out. For all the limiting factors there is

some minimum below which the potential for growth of the fertilized egg into a phenotype cannot be realized. If there is not enough energy of the appropriate kinds, if there is a deficiency even in a single material which is necessary, if there is not enough space, if there is not enough time, the growing phenotype will die before it matures and the fertilized egg will not contribute to the perpetuation of the species.

These concepts apply with suitable modifications to the evolution of social systems, just as they do to biological systems. With the biological development of the human race, an extraordinarily new evolutionary factor was introduced because of the remarkable capacity of this organism for developing both "know-what" and "know-how." No previous organism had anything remotely like the capacity of the human race for developing cognitive and valuational structures within its nervous systems. Humans can form images in their minds which correspond in considerable degree, not only with the whole human environment, but also which have the capacity of visualizing changes in this environment and carrying out these images of change in the production of human artifacts. Human artifacts comprise material artifacts, from flint knives to space shuttles; organizational artifacts, from the hunting band to NASA; and personal artifacts—that is, human beings with learned structures within them derived from other human beings.

With the development of the human race, evolution on our planet becomes increasingly what I have called "noogenetic." Even in prehuman evolution, a distinction between the purely biogenetic—that is, DNA and all that—and the noogenetic—that is, learned structures transmitted from one generation to the next by a learning process—has increasing significance. With the advent of the human race, however, noogenetic evolution becomes of overwhelming importance. In human beings the biogenetic evolution seems virtually to have ceased, at least in the last 50,000 years, and the biological gene pool of the human race has changed very little. In terms of human artifacts—material, organizational, and personal—however, the impact has been enormous. No part of the world ecosystem has been unaffected by it—cities, highways, agriculture, airplanes, chemicals—by this time hundreds of thousands of species of human artifacts have transformed the whole ecosystem of the earth, in what by biological standards is a fantastically short space of time. Many biological species have become extinct or are on the way to extinction; others may be on the way to creation, with the potentiality now for human beings intervening in the biogenetic structure.

Human artifacts are as much a part of the ecological system of the earth as are biological artifacts. They consist of populations of species interacting both with other human artifacts and with biological species. Even paleolithic humans created large-scale biological extinctions. With the development of agriculture and the neolithic, considerable changes in the recombinations and selection process of biological species (crops, livestock) took place. With the discovery of the use of fire, the input of organized energy into the system was increased enormously, with the subsequent development of cooking, pottery, metals, and a great variety of new artifacts. The rise of science in the last 500 years has created a positive explosion of new artifacts—chemicals, radioactive elements, machines, airplanes, computers, and so on.

The pattern of mutation (filling empty niches) applies just as much to human artifacts as to biological organisms. The niches for human artifacts are created to a very large extent by human demands and valuations. Whether these niches are filled depends on the changes in the noogenetic structure—that is, in the know-what and the know-how of the human race.

The production of human artifacts differs from that of biological organisms only in the complexity of the genetic structures. Biological evolution never got much beyond two sexes. The evolution of human artifacts is essentially "multi-parental." It involves the bringing together of know-how from a great many different sources. Human artifacts differ from biological organisms also in that their genetic structure is not contained in the artifacts themselves, but in other artifacts. The know-how that enables animals to reproduce is contained in the animals themselves. The know-how that permits the production of automobiles is not contained in the automobile, but in human beings and in plans, blueprints, libraries, and all the various prosthetic devices of human knowledge.

Nevertheless, the principle that production consists of the process by which the genotype becomes the phenotype is just as applicable to

human artifacts as to biological organisms. Although production originates in the genetic factor of know-how, it requires limiting factors of energy, materials, space, and time. If these limiting factors are not available in sufficient quantities, the potential for know-how will not be realized. An increase in know-how, however, can often push back the limits of the limiting factors, and indeed has done so constantly, both in biological evolution and in societal evolution. Prior genetic mutation through history permitted the biosphere to utilize forms of energy and materials which previously it could not utilize. In societal evolution, likewise, the growth of human knowledge and know-how has permitted a continual expansion of the niche of the human race and of its artifacts, by developing new forms of energy use, new materials, space-economizing and time-economizing techniques, and so on.

What does all this mean for economics, and especially for agricultural economics? Economics, I have sometimes argued, is the third oldest of the sciences, after physics and astronomy. Its theoretical structure crystalized in Adam Smith; it has not basically changed much since. Adam Smith had a clear concept of the system of commodities as an equilibrium system of quantities and prices, the equilibrium price system being that at which each commodity existed in an equilibrium population in which production and consumption were equal. Malthus applied this idea with particular cogency to what today we would call the concept of the "human niche." Both Adam Smith and Malthus were interested in development; that is, changes in the parameters of the system which increased its variety and complexity. It arose fundamentally, as Adam Smith saw, from the "quantity of science"; that is, human knowledge and know-how. In some sense, therefore, Adam Smith was the first in the scientific community to transcend a Newtonian equilibrium and to see the social system at least as an ongoing evolutionary process. He did not apply this to biological systems, for in his time, for instance in his contemporary Linnaeus, biology was only in the stage of achieving taxonomy, and did not develop any serious theoretical structures.

Unfortunately, Adam Smith, after the first three chapters of *The Wealth of Nations,* never developed his extraordinary insights regarding the impact of the division of labor on human learning and the essential role of human learning in production. We may perhaps blame the historical accident of structure of British agriculture in the eighteenth century, with its rather clear categories of landlords renting land to entrepreneurial capital-owning farmers employing landless capitalist laborers, for creating the taxonomy of factors of production as land, labor, and capital. In terms of the price system, this taxonomy has much value. Rent, profit, and wages do emerge as categories of some homogeneity and great interest from the point of view of distributional theory.

Who originally used the term "factors of production" and identified these as land, labor, and capital, I must confess I have not investigated. The concept, however, was formalized by Ricardo and became part of mainline economics under Mill. Marshall was never able to escape from this, although he tried to add a fourth factor, "organization," which he never quite identified as "know-how." Marshall was clearly uneasy about the Newtonian quality of equilibrium economics and felt that economics should use biological rather than mechanical models. He was never able to achieve this transition. Walras, unfortunately, by formalizing mathematically the mechanical aspects of general equilibrium, pushed economics into a still more Newtonian model. Keynes, again, never escaped from the equilibrium trap, and the supposedly developmental economics of Harrod and Domar can only be described as a disaster. It is totally incapable of illuminating the enormous complexity of developmental processes and leads to a neglect of the major element in them, which is the learning process.

The greatest disaster of all, of course, was Marx, whose labor theory of production must be blamed mainly on Ricardo, although Adam Smith is not blameless. It has been a major disaster for the human race and has created an evolutionary dead end in the communist societies, which bodes ill for the future. Marx, however, learning from Ricardo, at least saw the existing stock of human artifacts as the end product of innumerable acts of human labor, stretching back presumably to Adam and Eve. This was at least a primitive evolutionary perspective, seeing the present as a result of the history of the past. But as both Ricardo and Marx predated Darwin, and even Darwin knew very little about genetics, ecology, or morphogenesis, they can hardly be blamed for being primitive.

Both Ricardo and Marx missed the crucial

point which Adam Smith had begun to see, that it is human knowledge and know-how which is the real genetic factor, not "labor," which from the point of view of production is a hopelessly heterogenous aggregate. I have argued, indeed, that land, labor, and capital, from the point of view of the theory of production, are medieval aggregates with all the scientific validity of earth, air, fire, and water, and that they represent a totally inadequate taxonomy of the production process and of the evolutionary process. Once we look at production from the point of view of one genetic factor, know-how, and a set of limiting factors which may limit its operation, the whole process looks very different.

Another disaster was the development of what I have sometimes called the "cookbook theory" of production, in which Wicksteed, Walras, John Bates Clark, and so on, removed even the vestiges of Adam Smith's essentially evolutionary thought from economics. Here production has no history whatever. It consists of mixing land, labor, and capital in a cooking pot and out come potatoes or automobiles. The whole concept of a production function involving heterogenous aggregates of land, labor, and capital is pure economic alchemy and has been a total blind alley. The more sophisticated the theory of production got from Cobb-Douglas to constant elasticity of substitution production functions, the more useless it became, simply because it started off with a false taxonomy. No matter how elegant alchemy becomes, it will never produce synthetic plastics!

A further result of the cookbook theory of production was an almost total neglect of the problem of exhaustible resources. The ingredients were somehow always assumed to be in the kitchen—a kitchen, indeed, full of inexhaustible widow's cruses of land, labor, and capital, all willing to be poured into the cooking pot. It almost took the OPEC crisis of 1973 to awaken us to the fact that our boasted riches and productivity depended in no small measure on the exhaustion of exhaustible resources, not only in energy but also in materials.

The implications of the evolutionary perspective for agricultural economics could well be profound. In the first place, agriculture is the one sector of economic life which is inescapably close to the biological processes and in which, therefore, the relations between biological and societal evolution are of particular importance. Agriculture indeed consists of the application of human knowledge and know-how to changing the parameters of ecosystems in particular habitats in order to create a new quasi-equilibrium set of largely biological populations which is higher on the scale of human values. In other words, the business of agriculture is to transform an ecosystem so that it produces wheat instead of brambles, fat cattle instead of starving deer, sheep and pigs instead of buffalo and coyotes, thereby increasing the niche of the human race. This process involves a combination of noogenetic intervention, working through biogenetic processes. Up to now the impact of the noogenetic process has mainly been on selection, creating ecosystems with high populations of things high on the scale of human values, like food. To agriculture, of course, we should also add silviculture and the transformation of forest ecosystems and aquaculture, by which human know-how transforms the ecosystems of ponds, lakes, and rivers.

The parametric change which is introduced into these ecosystems by human intervention is complex and often produces unexpected results. Plowing rearranges the materials in the soil to make it more favorable to the growth of desired plants, but also may lead to soil erosion. Artificial fertilizers have pushed back some of the limiting factors of the materials affecting plant growth, but may also pollute streams and rivers. New seeds, hybridization, increase yields per acre by pushing back the space limitation, but through monoculture may increase the dangers of ecological disaster through exposure to new pests and diseases. An important aspect of humanly created ecosystems that is often neglected is their vulnerability to uncontrolled parametric change. The Irish potato famine of the 1840s was a classic example of an agricultural improvement which led to human catastrophe through vulnerability. One worries a bit about what might happen in the United States if we had a combination of a corn blight, a wheat rust, and a soy beetle all in the same year!

It is clear that agriculture must be regarded as part of the general evolutionary process of the planet, which has profoundly changed its aspect and its ecosystems, mainly through selection, in response to human valuations. We may indeed be on the edge of even more dramatic changes as a result of our potentiality for intervening in genetic as well as selective processes, through recombinant DNA, and

eventually, who knows, through chemical reconstructions of DNA. As a result, we may speed up biological evolution to an unprecedented rate. It is a very important question as to whether this may not make the whole system of the earth more vulnerable than it has been in the past. One of the remarkable phenomena in the evolution of this planet has been the capacity of the process to survive, and indeed even in some sense benefit from, catastrophe. If the record of the rocks is to be trusted—which it is not very much—the evolutionary process has been punctuated by catastrophes which separate one geologic age from the next. These catastrophes seem to have led to widespread extinction of the species of the previous age, which apparently opened up new niches, almost always for more advanced species, at least by human standards. Exactly why this should be so is by no means clear.

The evolutionary perspective in economics does not give us a Newtonian "celestial mechanics" of commodities; and this is because of the nature of the reality itself, which it is trying to describe, which is profoundly indeterministic. Evolution takes place by the filling of empty niches. There is no guarantee that empty niches will be filled before they close. This introduces a profound element of indeterminacy into the system, and any attempt to reduce it to a kind of Newtonian mechanics is bound to fail, simply because it is not that kind of reality. This is why, for instance, empirical attempts to explain development in terms of land, labor, and capital production functions have been so unsuccessful. We have always had to fall back on some vague concept of technological change, which is a kind of surrogate for the genetic know-how factor.

Agriculture is peculiarly important in the development of society because of the capacity for improvements in agriculture to create empty niches in many other fields and even to increase the capacity for filling existing empty niches. A good example would be what I have sometimes called the "turnip theory" of Western European, especially British, expansion in the last 200 or 300 years. The introduction of the turnip into Western European, and especially into British, agriculture in the early part of the eighteenth century, transformed the medieval three-field system into a four-course rotation. Turnips and other root crops enabled the previously fallow field to be used. The main reason for having the fallow field in medieval agriculture was to get rid of the weeds. With row crops and horse hoeing husbandry this could be done and still have a crop. Furthermore, clover could be introduced to restore fertility. This substantially increased the overall yield per acre, particularly in livestock feed. This permitted livestock to be kept through the winter instead of having to be slaughtered off at Christmas. This permitted breeding and improvement of livestock. This increased human protein consumption, which led to a diminution in infant mortality that was spectacular, especially in Britain in the mid-eighteenth century. This led to a population explosion which previous improvements in ocean transportation spread around the world to Australasia, North America, and South Africa. This created empty niches for new industrial production and so on to the present day.

An increase in yield per acre in agriculture will increase the size of the human niche, but an increase in yield per worker, because of the relative income inelasticity of the demand for food, diminishes the proportion of the population in agriculture, and expands the niches for nonagricultural goods. The filling of each new empty niche by invention (for instance, in textiles or in machinery) opened up new niches elsewhere, which again had repercussions in agriculture. Thus, the exhaustion of whale oil in the mid-nineteenth century due to the overkilling of whales opened up a niche for kerosene. It is not surprising, therefore, that the oil industry started in 1858. The development of chemistry permitted the transformation of crude oil into kerosene and gasoline, which at first was an unwanted byproduct. This created an empty niche for the internal combustion engine and the automobile, which in turn created empty niches for highways, the cement industry, supermarkets, and shopping centers. This also fed back into agriculture through the tractor and the substitution of fossil fuels and energy for horses, which released further food supply and led to further increases in the output per person, to the point where now in the rich countries something between 4% and 10% of the population produces all the food that is consumed, leaving 90% for other things. Only 200 years ago, food production took 80% or 90%, leaving only 10% or 20% for other things.

What then does this evolutionary perspective imply for the future of agricultural eco-

nomics? If there is indeed an empty niche, as I hope, for a genuinely post-Newtonian evolutionary economics, it seems reasonable to look to agricultural economics, with its rich biological involvement and its long tradition of both empirical and applied research, to pioneer in this development. This may mean the abandonment of some degree of mathematical rigor, which easily turns into rigor mortis when the real world that is being investigated is not itself mathematically rigorous and has large elements in it of randomness and unpredictable parametric change. This is not to defend sloppy thinking, casual empiricism, or merely analogical reasoning. Models, however, must be appropriate to the system that they attempt to describe, and there is a great opportunity here for the development of a mathematics which is appropriate to evolutionary reality. If the theory of fuzzy sets can be expanded into a theory of fuzzy processes, we may be much closer to the real world than we are when we try to find stable parameters which do not exist in nature. A symbolic representation of evolutionary reality in a simplified manner is very much needed and should be a real challenge to the mathematicians, for the mathematics which is really appropriate to evolutionary and to social systems does not yet exist. The social sciences in the twentieth century have been captured by essentially seventeenth-century mathematics, with a little dash of nineteenth-century probability and statistics, much of which is quite inappropriate to the type of real world which is being investigated.

Agricultural economics strikes me as being the ideal starting point for empirical investigation into both limiting-factor models and exhaustible-factor models, both aspects of what might be called "genetic production theory." It is obvious in agriculture that human know-how has been the critical factor in agricultural production. This know-how, however, is limited in its realization by the limiting factors of energy, materials, space and time, but is also constantly engaged in pushing back these limits. An important aspect of limiting-factor theory is that it is the most limiting factor which is important. If we are climbing a mountain, even if it is a utility mountain, it is the first fence that we come to that stops us. Other fences might lie beyond this and if we push back the first fence they may become the most important, but at any one time it is the first limiting factor that demands the major part of our attention.

An increase in the know-how or genetic factor, of course, may change all the limiting factors, for they all interact with each other. Hybrid corn, for instance, certainly economized space. It also economized time, being quicker and easier to harvest. It may even have economized energy input, utilizing more solar energy and less muscle or fossil fuel power, but I am not sure of this. It probably did not economize materials, but increased the necessity for artificial fertilizers. What we have here is a complex shift in the fences that crisscross the productivity hill. They are by no means easy to unscramble. Unscrambling these effects would be much more rewarding than trying to develop Cobb-Douglas production functions, or any kind of constant parameter function. Sometimes, indeed, the most important limiting factor could be an undetected trace element.

Another large field of research which opens up is the study of the impact of relative price structures, particularly of their certainty and uncertainty on agriculture. The relative price structure operates through wages, prices, profits, and rents. Its impact on production is mediated through its impact on the limiting factors. Yet this is something which the cookbook theory of production completely overlooks. Labor is a complex aggregate of know-how, muscular energy released through the burning of food, material structures that determine health and vigor, diet and nutrition. In Adam Smith, and oddly enough even in Jevons, labor was a kind of input-output apparatus to transform food into other things. Feeding agricultural workers produced more food. Feeding industrial workers transformed food into textiles or metals or machines, if the laborer was employed in these areas, very much in the way that a cow was an input-output machine for turning grass into milk and meat. This at least was closer to the complexity of the real world than the assumption that labor was an independent measurable factor of production, which when stirred in with capital and land became cheese. The opportunities for empirical research guided by the limiting-factor theory seem to me to be very great.

Finally, agricultural economics is an excellent field for the study of the economy as a subset of the larger evolutionary ecosystem of the world, particularly for what I have been calling "echo effects." If agricultural economics cannot be part of a general ecological science, there is not much hope for us. Ecological systems are also "echo systems," in which

any act or event echoes and re-echoes all over the system, and the final effect may be extremely different from the initial disturbance. We see this particularly in the problem of distributions of economic welfare, which often end up very far from an initial intended act. Agricultural policy is an extraordinary case in point, where, for instance, price supports that originally were conceived to help the poor in fact have helped the rich farmer and chased the poor farmer out of agriculture, perhaps—or perhaps not—to be better off elsewhere. Such policies have benefited the nonagricultural population much more than the agricultural population, have created all sorts of strange redistributions among the owners of land, like the impact of the tobacco quota, and have ended up with a very different kind of overall ecosystem than their authors imagined. Agriculture is also a good example of a reverberant system, where the echoes do not die away but set the system on a course of irreversible evolutionary change.

It is a fundamental principle of evolutionary theory that our capacity for predicting the future is extremely limited. Celestial mechanics had only the success that it had in predicting eclipses because the evolution of the solar system had virtually ceased. Agricultural economics deals with one of the most significant and rapid evolutionary systems in the world and should, therefore, be skeptical of prediction of any kind. Nevertheless, it does lead us to the search for empty niches and for the possibilities of filling them, and this may be a much more important guide to policy and to human behavior than mechanical prediction. The guide to societal evolution is search, both historically and in work on the future. Agricultural economics has a peculiar opportunity to study and improve the process of search for empty niches and for new mutations. Newtonian economics may have come to a dead end. But every evolutionary dead end seems to have created a search for an open road, and in this last reflection one can indulge in a good deal of hope and optimism. This is an age of Jeremiahs, quite legitimately, if we are confined to contemplating the future of the world as if it were not an evolutionary system. But the evolutionary model emphasizes the unexpectedness of the future, and in unexpectedness there is always hope.

Funding for Agricultural Economics: Needs and Strategies for the 1980s

Bernard F. Stanton and Kenneth R. Farrell

Public funding for work in agricultural economics—teaching, research, and extension—appears to be declining in real terms at the start of the 1980s following two decades of real increases. There is a call for reductions in spending by government at all levels—a call for less taxes and for public accountability. At the same time there are more students in the courses that agricultural economists teach. There is a renewed interest in agricultural business curricula. Graduate study in agricultural economics is attracting new students from the biological and social sciences as well as agriculture. The demand for competent, applied economists, particularly agricultural economists with advanced degrees, appears to be growing.

The anomaly of apparent increases in demand coupled with declining public funding presents a challenge to the profession. It should be one for which economists are prepared. After all, we regularly teach students about economic decision rules for allocating scarce resources among competing ends. The political environment requires that we take our classroom lessons seriously and put them in practice in our own operations.

This paper explores several approaches and strategies for funding work in agricultural economics and more effective use of current resources. We begin with an overview of changes in funding during the decade of the 1970s drawing upon secondary data and results of a mail questionnaire sent to agricultural economics department chairmen and administrators in the spring of 1981. We turn, then, to discussion of the demand, current and prospective, for services of agricultural economists and the capacity of current institutions to service that demand. We conclude with discussion of funding strategies and recommendations on actions which might be pursued by the AAEA.

Overview of Funding in the 1970s

During the decade of the 1960s federal appropriations for agricultural research from all sources increased in real terms. In the 1970s, in contrast, they held roughly constant. Over the same time span total nonfederal support continued to rise in real terms. Most of this support was from state and local sources, but it also included small but significant increments from private foundations and industry groups. Although similar data are not readily available for extension and resident instruction and the relative proportions supplied by state and local versus federal sources is somewhat different, the same basic trends should hold with nonfederal sources providing an increasing share of the total in the 1970s.

In 1970 USDA had appropriations of $281 million, or 1.8% of total federal funding. In 1980 research at USDA was funded at $664 million, or 2.2% of the federal total. Relatively, agriculture gained in the 1970s along with other nonmilitary federal agencies as a smaller percentage went to defense and space.

Research Funding—CRIS Aggregates

Public sector expenditure for agricultural research is largely the work of either USDA or state experiment stations. In terms of 1979 dollars, funding for agricultural research increased by 27% during the past decade. Biological science accounted for about 70% of the total, physical science varied between 18% and 22% and social science the remaining 8%–12% (table 1).

When funding for research in agricultural economics was separated out of the totals for

Bernard F. Stanton is a professor of agricultural economics, Cornell University, and Kenneth R. Farrell is Administrator, Economic Research Service, U.S. Department of Agriculture.

The authors acknowledge the able assistance of Bernardine Holland in typing several drafts of the paper.

Table 1. Public Sector Expenditures for Agricultural Research (All Sources, CRIS Data, United States, 1970–79)

Year	Biological	Physical	Social and Other	Total
	(1979 $, millions)[a]			
1970	684	204	80	969
1972	716	216	91	1,023
1974	738	213	94	1,045
1976	773	229	117	1,119
1978	860	248	146	1,256
1979	885[b]	226	122	1,233

social and behavioral sciences, there was an increase in the total (1979 dollars) of more than 45% during the decade, compared with 27% for all agricultural research. Thus, economics amounted to a little more than 6% of all agricultural research expenditures in the first half of the 1970s and over 7% in the last half (table 2).

A distribution of the funding of agricultural economics research by source is presented in table 3. In terms of 1979 dollars there were important increases in all of the sources listed in these unpublished CRIS data. USDA "in-house" funding for economics research increased about 50% in real terms. The Economic Research Service accounted for 69% of that total in 1970 and 75% at the end of the decade.

Agricultural economics research funds distributed to the state experiment stations by the USDA, both formula funds and all types of grants, contracts, and cooperative agreements increased modestly (27%) in real terms,

Table 2. Public Sector Expenditures for Agricultural Economics Research (All Sources, CRIS Data, United States, 1970–79)

Year	Expenditures current terms	Expenditures 1979 dollars[a]	Percent of total agricultural research
	($ millions)		
1970	35.8	63.8	6.6
1972	44.7	72.8	6.1
1974	50.8	72.0	6.9
1976	69.6	85.8	7.7
1977	74.4	86.6	7.1
1978	87.0	94.3	7.5
1979[b]	93.7	93.7	7.6

Table 3. Sources of Funding for Agricultural Economics Research (Public Sector Expenditures, CRIS Data, United States, 1970–79)

Sources of Funds	1970	1976	1979
	(1979 $, millions)[a]		
USDA: (internal)			
Economic Research Service	21.1	30.5	33.1
Agricultural Research Service	2.3	2.2	3.2
Forest Service & Farmer Coop. Service	7.2	7.2	7.7
Total	30.6	39.9	44.0
USDA: (external)			
Cooperative research	12.6	16.4	14.6
Grants, contracts, agreements	1.2	1.5	2.9
Total	13.8	17.9	17.5
Other federal departments & agencies	2.3	6.0	7.1
Nonfederal	17.1	22.0	25.1
Total	63.8	85.8	93.7

[a] Using the GNP Implicit Price Deflator.

equivalent to the aggregate increase in the decade for all agricultural research. Agricultural economists at the state experiment stations and land grant universities turned increasingly to their own state governments and other federal agencies for funding during the decade. In 1970 federal agencies other than USDA accounted for only 3.6% of total funding but this increased to 7.6% of the total in 1979. Nonfederal sources increased by 47% over the period, the same rate as total research funding grew in real terms.

Information on Funding—Agricultural Economics Departments

A survey of chairmen of departments of agricultural economics was conducted using a mail questionnaire during the spring months of 1981. A total of fifty questionnaires were returned from 1890 and 1862 land grant universities and a few other departments with programs in agricultural economics. Comparative data were obtained from forty departments (table 4).

Agricultural economics departments have not fared particularly better or worse in funding than other academic departments in their respective colleges over the past decade. Agricultural economics had a larger budget relative to the rest of the agricultural college in 1980 compared to 1970 in eighteen cases but it was smaller in fifteen others. Changes in both directions were generally modest.

Departments were asked to allocate their

Table 4. Student Numbers: Agricultural Economics Departments (40 U.S. Universities, 1970 and 1980)

Region	Number of Schools	Number of Majors Advised 1970	1980
Undergraduate students:			
Northeast	7	708	1,290
North Central	9	1,806	2,962
South	14	1,091	2,546
West	10	1,416	2,481
Total	40	4,821	9,279
Graduate students:			
Northeast	7	187	239
North Central	9	654	776
South	14	375	675
West	10	234	353
Total	40	1,450	2,043

budgets to the three major functions of teaching, research, and extension, as well as international programs and note important changes in these distributions. Only modest changes in the percentage distributions occurred during the decade. The median allocations in 1980 were 47% for research, 24% for extension, 18% for teaching, and 11% for all other activities including international programs.

It is difficult to establish the percentage of time individual faculties spend on each function, such as teaching. The numerical data on the changes in student numbers advised by agricultural economists at the forty colleges and universities indicate a substantial increase in the teaching commitment over the decade, even though the percentage allocations to teaching do not fully reflect this. In all of the regions undergraduate numbers increased significantly. The number nearly doubled nationally, with the largest percentage increase in the fourteen departments in the South. Every department reported an increase in undergraduate majors. The increase in graduate student numbers during the decade was also substantial, a little over 40% nationally. It is likely that resources from these commitments have been "borrowed" from research.

In terms of sources of budget support for all the programs and functions of individual departments, state resources are the primary source of funding, on the average, in all of the regions. Funds allocated to departments from the USDA were a smaller part of the total budgets in all regions, dropping from 34% to 28% nationally. Other federal agencies and departments provided some of the added support from grants, contracts, and other types of agreements.

Funding for research is more completely documented than for extension or teaching. Departments nationally obtained 45% of their funding from state sources in 1970, compared with 43% in 1980. USDA formula funds and grants also decreased from 42% of the total in 1970 to 38% in 1980. Other federal agencies, which accounted for 7% of research funding in 1970, provided 14% in 1980. Energy, natural resources, transportation, international development, and environmental protection were the chief sources of this support. Only limited funding, less than 0.7% in 1980, came from the National Science Foundation (table 5).

Respondents were asked to allocate funding for research into five general areas of work in agricultural economics in both 1970 and 1980. In the Northeast there was a marked swing away from marketing and farm management to natural resource economics and land use issues. In the North Central region, marketing and prices and supply-demand analyses were the most important general areas of work in both 1970 and 1980. In this region alone, marketing did not show a decline in relative importance. In the South farm management and

Table 5. Changes in Sources of Budget Support: Research, Extension, Resident Instruction (40 Departments of Agricultural Economics, 1970 and 1980)

Region	Source of Budget	1970	1980	Net Change
		--- (% of total) ---		
Northeast	State	56	62	+6
	USDA	38	30	−8
	Other federal	2	2	0
	All other	4	6	+2
North Central	State	60	58	−2
	USDA	28	25	−3
	Other federal	7	11	+4
	All other	5	6	+1
South	State	53	54	+1
	USDA	42	36	−6
	Other federal	2	9	+7
	All other	3	1	−2
West	State	65	63	−2
	USDA	25	20	−5
	Other federal	6	14	+8
	All other	4	3	−1
Total	State	58	58	0
	USDA	34	28	−6
	Other federal	5	9	+4
	All other	3	5	+2

production economics increased in importance over the decade. In the West there was a major shift away from marketing toward natural resources and farm management.

Nationally, farm management and production economics held quite steady over the decade as a major research area. Marketing received less of the research resources, and there was an important shift in work toward land use issues, rural development, and natural resource economics in all of the regions. In a relative sense the increase in work in agricultural policy, regional economics, and macroeconomic issues was also of special note.

During the past decade agricultural economists have increased their participation in both research and extension projects involving scientists in other agricultural disciplines. This is true across all the regions and in most departments. In looking ahead, thirty-three of the department chairmen expected further increases in the amount of research involving other disciplines. Seven expected the amount to be roughly the same as now.

Setting of the 1980s

The foregoing data suggest that agricultural economics did as well or better than other agricultural science disciplines in competing for scarce resources in the 1970s. And there is evidence of adaptability and resiliency of the profession with respect to both sources of funding and subject matter emphasis.

Demand for Services

At the risk of appearing self-serving, we believe that aggregate demand for services of agricultural economists will continue to expand in the 1980s. However, the composition of that demand may change dramatically.

Our optimism with respect to growth in demand for agricultural economic services is predicated upon the expectation that food, agriculture, and natural resources will occupy critical roles in economic systems both in the United States and abroad during and beyond the 1980s. Food production, even in the United States, cannot be taken for granted as multiple use competition for natural resources intensifies.

Commercial production, marketing, and distribution of food and fiber have always been and still are the cornerstone of agricultural research and education programs (70% of total research). If the evolution toward less direct intervention by government in the agricultural economy continues in the 1980s, as now seems apparent, the private sector demand for timely, reliable, market-related economic information is likely to increase substantially. In the public sector, demand for economic information will continue strong as a basis for monitoring performance of the food and fiber system, policy analysis, and for targeting and evaluating public programs.

Our international interdependence also will be a source of continuing demand for economic information, research, and analysis in both the public and private sectors. Issues related to trade policy, food security, international market instability, market development, the organization and performance of international monetary and financial institutions, and the interdependence among trade and domestic food and agricultural policies are key areas likely to require additional attention of agricultural economists, particularly in the public sector. The private sector will require from corporate economists and from those in the public sector more detailed and specific data and analyses to guide market development and foreign investment activities.

We expect American agricultural economists to continue to be called upon for technical assistance and "institution building" in the developing countries of the world. For many of those countries, agriculture is the "cornerstone" of economic development. Heavily affected as many have been by petroleum price increases and a large foreign debt-servicing load, most developing countries face critical economic choices involving food and agriculture.

The major onus of responsibility for development of economic information, research, and policy analysis concerning natural resources rests in the public sector. That is not to say that the private sector is unaware of, unconcerned with, or without need for relevant economic information concerning the economics of natural resource use but merely to remind that market forces that drive many of the "on-site" decisions concerning natural resource use fail to capture externalities associated with those decisions. With much of the "slack" already removed from the U.S. agricultural production plant, we know much less than we should about the characteristics

of the long-run supply functions for land and water and the associated conservation, environmental impacts, and costs under conditions of sustained increases in agricultural production.

Department chairmen and administrators were asked in our survey to indicate the most important areas toward which additional work in agricultural economics should be directed in the 1980s. These judgments provide further insight into areas of work where increased demands seem evident.

(*a*) 39% suggested commercial agricultural production and marketing as areas requiring additional work.

(*b*) 22% identified agricultural policy and structure issues as highest priority.

(*c*) 19% identified with energy and natural resource issues.

(*d*) For the remaining 20%, undergraduate teaching programs and international trade and development were about equally distributed.

A wide range of specific problem areas were listed as most likely to require increased work by agricultural economists with scientists in other disciplines. Most frequently these were problems involving some aspect of production economics. Commonly, there was an energy-related component of the problems. Resource management issues, particularly about land and water, were high on many lists. A wide range of environmental concerns from integrated pest management to acid rain were noted.

Strikingly, not a single department chairman or administrator indicated that rural development should be given high priority. Whatever the future may hold for funding of rural development, it clearly is an area in which the application of economics should be highly relevant and to which agricultural economists have the capability to contribute, given their considerable talents in relating "economic theory to observable facts" and their knowledge of rural institutions. Surely agricultural economists, as social scientists, have a unique responsibility to understand and assist in the resolution of economic problems of people and institutions in rural areas.

Structure and Organization for Delivery of Services

tor continues as the major source of employment, economic data, situation and outlook information, and basic economic analyses. As an integral part of the USDA-land grant partnership fashioned in the late 19th century and tailored to its present institutional form in the first third of the 20th century, the public agricultural economics "establishment" of today bears many of the same strengths and deficiencies as the larger system. Several of the characteristics are worth noting as we reflect on needs, priorities, and funding of the 1980s.

Decentralization. Institutionally, public sector agricultural economics work is conducted in sixty-four land grant universities (fifty "1862" and fourteen "1890"), about fifteen other state universities and colleges, the federal government (primarily USDA), most state governments, perhaps ten to twelve nonprofit research and education institutions, and a few private universities. This decentralization of work is in many ways a strength of the establishment, tending to encourage responsiveness to local needs, independence, and intellectual freedom, and precluding singular, authoritarian dogma in theory and methods. But in other respects it complicates communication and coordination, contributes to duplication of effort, and inhibits development and implementation of concerted, discipline-wide initiatives.

Specialization. In most universities and in the USDA, agricultural economists have been most commonly grouped in units or departments that center around the discipline of economics. The disciplinary organization of our work is not inconsistent with the view of agricultural economics as an "integrating science." And, it has permitted us to develop theory, methods, comprehensive data sets, and a macroview of agriculture which might not have been achieved otherwise. At the same time, there has been a tendency for isolation from other disciplines and "problem-oriented" agricultural departments and units. That tendency inhibits interdisciplinary, mission-oriented research of the type needed to resolve many of the problems of the 1980s.

Pluralism. The "establishment" is diverse and pluralistic in mission, goals, methods, and funding sources. Most land grant departments

to each function. University programs emphasize state and local issues: USDA programs have a national and international focus. Research in universities is small in scale, heavily supported by graduate students, and oriented to the discipline, methodology, and longer-run problems. USDA research tends to be heavily applied, larger in scale, short-run, sometimes "crisis" oriented, with greater emphasis on policy analysis and primary data collection.

Again, there are strengths and benefits from pluralism. But these same strengths make it difficult to obtain clear national or disciplinary focus on programs, specify priorities or develop system-wide strategies.

Strategies for Funding and Problem Solving in the 1980s

Several indicators of tighter funding for agricultural economics work in the 1980s could be cited. As a proportion of college budgets, funding for agricultural economics during the 1970s declined in fifteen of the thirty-three departments responding to our survey. In late 1980, Michigan State University was forced to furlough staff and severely restrict support services as a result of falling state revenues. Other states have been similarly, if less drastically, affected by "proposition 13"-type reductions in state revenue. At the federal level, the Reagan administration has proposed sharp reductions or smaller-than-expected increases in budgets for many nondefense-related functions and departments. To bring matters "closer to home," the Reagan administration has proposed to reduce National Science Foundation grants for social, economic, and behavioral research from $49 million in 1981 to $16 million in 1982. The *Washington Post* reported that "OMB Director David A. Stockman and others have complained for years that social sciences produce little or nothing, and that their studies are often used to support liberal social programs." At the same time the *Post* reports, the administration has begun a "social science hour" at the White House to better understand the background social facts against which policy will be mapped.

Still "closer to home," ESS (now ERS and SRS) recently conducted a two-day public meeting to obtain suggestions for establishing priorities on statistics and economic research in ESS and activities which might be reduced or eliminated in the event that a 20% budget reduction were necessary in fiscal year 1983. Concurrently, the administration's budget proposals for fiscal year 1982 included increases for agricultural economic research as well as all agricultural research.

Although the funding levels for agricultural economics work for the immediate future are not yet clear, the direction toward tighter budgets and closer public accountability is evident. If, as we have suggested, demand for agricultural economics services continues to grow, we face difficult choices and the classical economic problem of allocating scarce, possibly scarcer, resources among competing uses.

Obviously, no single initiative or funding strategy will suffice. Each institution will need to develop plans and strategies adapted to its particular or unique circumstances with respect to clientele, priorities, and the quantity and quality of available resources. Nevertheless, there are several common and some multi-institutional or discipline-wide plans and strategies that warrant consideration and action.

Monitor Funding and Resource Allocation for Agricultural Economics Work on a Regional and National Basis

Communication within our decentralized system is difficult and highly imperfect. Yet, the availability of reliable, timely information is essential for planning and decision making. The need for such data is particularly important at this time when important decisions on funding and resource allocation may be taken in the context of tight budgets. These data are also essential for any informed, rational plan or strategy that might be undertaken subsequently by the profession or groups of professional institutions.

The CRIS is an embryo of a useful system for these purposes. It contains, however, superfluous information and is subject to excessive reporting lags. We suggest AAEA consider an annual survey of institutions having substantial resources devoted to agricultural economics, to obtain information on funding by functions and source and on allocation of resources by subject matter field. These data might be reported at the annual AAEA business meeting. The questionnaire developed for use in preparing this paper

could be a point of departure. The CSRS/USDA might be approached for funding assistance.

Initiate Efforts to Identify High Priority Research and Extension Needs for the 1980s

The profession has been loathe to undertake such efforts in the past. Certainly some of our past experiences, the pluralism of our work, and the reluctance of some leading figures and entrepreneurs in our profession make it a risky venture. However, the invitation of the director of USDA's Science and Education Administration to professional societies to develop a statement of priorities engendered a substantive statement from the AAEA Board in 1980–81. Greater involvement by more individuals in the profession should be fostered in future efforts.

To be useful and credible, a statement of priority needs must be more than a "laundry list" of what economists do or an amalgam of platitudinous wishes. It should be keyed from a careful, comprehensive review of likely directions of agriculture, natural resource use, and rural America in the 1980s; the principal data and research needs to which those trends give rise; and a sober assessment of our capacity to respond to such issues. It must avoid being self-serving or condescending in tone, and it must above all be rigorous and professional in content. With regional elaboration, one version could serve the profession as an indicative research planning tool. But a second version also is needed—one which is issue- and output-oriented, stressing decision makers to be served, and the value of output to those decision makers. Where appropriate, scientists from other disciplines should be involved in preparing these statements, especially the latter. Such statements should be updated and refined periodically to reflect changing needs and priorities.

Whatever approach is taken should involve the AAEA as an active participant. One approach might be for AAEA to "commission" a group of scholars nominated by the membership to draft the statement. Or, groups of scholars by subject matter field might be nominated to draft a series of statements to be integrated by another AAEA-appointed group. In any event, the statement should be the subject of written comments or conference dialogue by AAEA membership before final approval. Another variant would be to invite the regional associations to draft statements with a synthesis made nationally by AAEA. Recent prototypes of statements of this type include *Soil and Water Resources: Research Priorities for the Nation,* sponsored by ten professional societies including the AAEA, and *Animal Agriculture, Research to Meet Human Needs in the 21st Century,* sponsored by five professional societies, several experiment stations, and the USDA.

Assume a More Positive Stance in Funding of Agricultural Economics Work

Unless we are prepared to exert influence with those who make decisions on the funding of agricultural economics work, the development of improved information and statements of needs and priorities are of little avail, however elegant they may be in formulation and exposition. Other scientists have perceived this simple truth more readily than we. For example, the American Society of Animal Scientists has appeared on several occasions before SAES/USDA research planning entities to present consolidated statements on research needs and priorities on behalf of its membership. The land grant forestry schools and the U.S. Forest Service have worked closely over the past decade under aegis of the Joint Council and its predecessor organization to develop comprehensive statements on forestry research needs on regional and national bases. Those statements have been used consistently for development and presentation of budget proposals in the USDA, SAES, and before congressional committees with considerable success.

We know of no occasion in the past decade when a state agricultural economist has appeared before the House or Senate subcommittee on appropriations to support or comment upon the budget proposals of ERS or CSRS. Nor has the reverse occurred to our knowledge.

Direct support for agricultural economics research in the budget-making process is diffuse and weak. With the exception of ERS and CSRS, most budget proposals for economic research are "brokered" to appropriations bodies through deans or directors. Frequently those proposals are presented as "riders" to proposals from the physical and biological sciences where support may be higher. Typically, it is more difficult to convey the purpose and value of economic research to legislators

than for sciences in which output can be expressed in demonstrable physical terms. And, whereas farm and commodity organizations appear regularly before appropriations committees to support physical or biological science needs and proposals, few appear before such bodies in direct support of economic research. Even our statistician colleagues enjoy stronger, more direct, external political support than we do in the budget-making process. We should consider how best to build external support for our work and more effective representation of our interests in the budget-making process.

We recognize the constraints, professional and legal, which pertain to "exertion of influence" in the budget-making process. We do not advocate politicization of the profession. But, indirectly and properly, we can be more active in supporting the funding of agricultural economics work. For example, we might interact more extensively with IR-6, the SAES venture to support and coordinate SAES/SEA budgets for agricultural research. Perhaps we should seek more active involvement in the Joint Council on Food and Agriculture Sciences and its related bodies including the National Research and Extension Coordinating Committees and the regional councils and committees. Other institutions in which social science research and extension needs and priorities might be injected more effectively include the regional and national associations of land grant experiment station and extension service directors. Support from various interest groups might be explored.

Currently, funding of agricultural economics through the P.L. 89-106 Special Grants program is limited to one project—NC-117. Under management of CSRS, P.L. 89-106 authorizes "earmarked" funding of mission-oriented research in several disciplines. We believe that, in collaboration with CSRS, we should explore further this source of funds to support mission-oriented agricultural economics research. Further, we suggest that ERS and the land grant universities explore funding of joint projects through ERS appropriation requests.

Effective joint planning and leadership are required for any of these approaches to succeed. AAEA, the regional professional societies, regional committees, informal research groups, as well as ERS and CSRS are potential sources of such leadership.

At the state level an important source of new funding is from business, industry, and commodity or special interest groups. Often, small marginal increments from these sources will permit initiation or conduct of research or extension projects which might not otherwise be undertaken or fully completed. However, it is essential that management and publication control of research or extension projects funded by the private sector or, for that matter, funded by public agencies with action programs or special mandates, be retained by the research or extension agency. T. W. Schultz has spoken succinctly of the issue in a recent paper:

> The core of my argument is that one of the primary functions of academic economists is to question society's institutions. Economists are all too complacent about their freedom of inquiry. They are not sufficiently vigilant in safeguarding their function as educators. . . . The distortions of economic research will not fade away by accommodating patrons of research funds.

Develop Fewer, Larger Research Projects with a Regional or National Orientation

One of the important needs of the 1980s is to develop new mechanisms to allow extension specialists and research workers to make more effective use of their skills and knowledge across state and county lines with appropriate funding transfers which recognize these contributions. This is a longer-term problem with no simple solutions. Castle, in his impressive Kellogg Foundation Lecture to the National Association of State Universities and Land Grant Colleges, speaks clearly about this issue. The need to build credibility, make use of our specialized knowledge and comparative advantage within universities and disciplines, and reduce state and federal conflicts was emphasized. But we cannot simply wait for administrators to find ways to build bridges to allow greater specialization and reduce overlaps in research and extension. We should ourselves take the initiative. We have several suggestions.

Although performance of regional research projects has been uneven, we should continue to experiment with these devices. An objective should be to build a regional system for research and extension without the formal structure and bureaucratic processes which have encumbered many regional projects. The NC-117 model, with a permanent core staff, full-time executive director, and funding from the SAES, USDA, "off-the-top" regional

funds, and 89-106 Special Grants funds, has been highly successful in providing continuity of effort and coordination among participating institutions. Planning and commitments by the participating institutions are on a rolling three-year cycle—long enough to permit conduct of research but short enough to avoid permanent institutionalization of the project. That model might be adapted to research on other major problems.

A related, still-evolving mechanism to improve coordination and additivity in research is that of the International Trade Research Consortium, involving about ten U.S. and Canadian universities and the USDA (ERS and FAS) and jointly funded by those institutions. The Consortium evolved as an informal vehicle to bring together researchers having a major interest in and commitment to international trade research. Several workshops have been conducted and a research agenda has been established with the intention of seeking funding from government, nonprofit foundations, regional, and university sources. Without the formal structure of a regional project, but with a small core staff to provide continuity and assist in coordination of effort, this model of a successful working group might be adapted to other situations as a means of seeking major funding when project proposals are reviewed competitively.

A substantial amount of our resources is invested in development of quantitative economic models. Current requirements for development and maintenance of complex economic models are, in some cases, well beyond the technical and financial capabilities of any single agricultural economics research institution. We need to explore new institutional arrangements not only among U.S. institutions but with international research institutions as well.

Initiatives and multi-institutional innovations such as these usually turn on the leadership of a few individuals. We should do more to encourage such innovations. The AAEA is a logical forum in which to explore these and other types of institutional innovations through workshops, symposia, "commissioned" papers, and other approaches.

Participate Actively in Developing Research and Extension Proposals with Scientists in Other Disciplines

There is need for a small, but important, fraction of agricultural economists to commit themselves to take the initiative back at the project proposal stage to provide integration of economics and other disciplines. This will require specialization where an individual or a small team puts in perhaps 50% to full time on projects that span three to five years. The need for such leadership and commitment cuts across all aspects of the discipline: production, marketing, natural resources, and policy. In cases where such leadership originates in agricultural economics, more than token funding is likely to follow. Integration in the form of 10% of a scientific man-year annually is likely to lead to tokenism, with little impact on the project.

If public funding for research and extension is increasingly targeted to special problems as perceived by Congress and state legislatures, then agricultural economists must take leadership in developing proposals to solve these problems and help to define special projects for study. This will require specialization and a commitment to learn more about applied biology and engineering. It will be a mandate for a small percentage of all agricultural economists to be integrators with both fellow economists and those working directly with scientists from other disciplines.

In the near term at least, funding prospects appear brighter for the physical and biological sciences than for economics. On a purely strategic basis for future funding as well as for the reasons cited previously, we should consider seriously means of aligning ourselves more closely with those sciences. AAEA could encourage interdisciplinary work by regularly including a forum in its meetings for reporting the results of such work and extending its liaison representation to other professional societies. Some special recognition of published research in this area might provide further stimulus.

Concluding Comments

Comparatively speaking, we fared reasonably well in the funding of our work in the 1970s. But the 1980s pose new challenges and opportunities for us—prospective growth in demand for services and scarce, possibly scarcer, real resources.

To meet those challenges and opportunities requires that we be prepared to innovate institutionally; that we seek new approaches to conducting our work within the discipline and with other disciplines; that we set forth some

central directions and priorities to enhance our image and credibility with potential funding sources, old and new; that we attempt seriously to plan and, yes, even coordinate, our work in a manner to enhance our collective productivity and efficiency.

Passive observation of the changing environment of agricultural economics work will not improve our productivity or improve decisions in the allocation of scarce resources. But neither will short-run actions of expediency! What seems to us to be required is that we begin to view our individual services as collective services, not just for disciplinary purposes, but in the interests of agriculture, rural America, and the public at large. So viewed, collective action in the development of appropriate funding strategies seems appropriate.

The key to our suggestions is, of course, leadership—effective, forward-looking leadership—at numerous junctures in the profession. AAEA is one such juncture. It is in that vein that we have made our case and our recommendations.

Funding for Agricultural Economics: Discussion

Joseph Havlicek, Jr.

Farrell and Stanton are to be complimented on an excellent paper dealing with (*a*) funding patterns and changes in support for research in agricultural economics and nonagricultural economics areas during the 1970s, (*b*) factors influencing the demand for services of agricultural economists and the capacity to service that demand, and (*c*) some strategies for funding agricultural economics research and for better utilizing resources currently available for agricultural economics research. I have no quarrel with any parts of their paper, and the focus of my discussion is on shedding additional light on some of their major points.

The analysis of funding patterns of agricultural economics and nonagricultural economics research by Farrell and Stanton is based on data obtained from a survey of heads of departments of agricultural economics and unpublished CRIS data on funding of agricultural economics research. To complement their analyses, I have analyzed the patterns in funding of agricultural economics research from 1970–79, as exhibited by the expenditures in twenty-three research problem areas (RPAs) which encompass agricultural economics research. The twenty-three RPAs analyzed were 108, 114, 316, 503, 506, 507, 508, 509, 510, 601, 602, 603, 604, 703, 801, 802, 803, 804, 807, 808, 902, 907, and 908. The data were obtained from the Inventory of Agricultural Research, volume 2, tables 2, 3, and 4, FY 1970–79. Some of the RPAs encompass other than agricultural economics research, but the total funds allocated to the RPA were used because there is no basis for separating out the funds allocated to agricultural economics research. The funds allocated to agricultural economics research covered by the RPAs include allocations to departments and research units other than departments of agricultural economics and agricultural economic units in the USDA. Also, the constant dollars were obtained by using the implicit deflator for government purchases of goods and services, which is a different deflator than the one used by Farrell and Stanton.

Farrell and Stanton found that the proportion of all agricultural research funds allocated to agricultural economics research was about 6% in the first half of the 1970s and a little more than 7% in the last half of the 1970s. Based on the data for twenty-three RPAs, the comparable proportion for the same time period ranged from 6% to 7% in the State Agricultural Experiment Stations (SAES) but from 9% to 13% in the USDA. Also, on a regional basis the South and the West had the lowest figures, 5% to 6% and 4% to 5%, respectively. In the North Central Region 7% to 9% and in the Northeast 7% to 10% of all agricultural research funds were allocated to agricultural economics research. None of these percentages exhibited any apparent trend during the 1970s, and thus agricultural economics research does not seem to be faring any better relative to other agricultural research.

In terms of changes in constant dollars, Farrell and Stanton found that funds allocated to agricultural economics research increased about 45% from 1970 to 1979, while constant dollars allocated to other agricultural research increased about 27%. The percentages based on the twenty-three RPAs are somewhat lower. In the SAES, the constant dollars allocated to agricultural economics research increased 42% from 1970 to 1979, and constant dollars allocated to other agricultural research increased 28%. The comparable percentages in the USDA were a 32% increase in constant dollars for agricultural economics research and only an 8% increase for other agricultural research. But some striking differences exist among the four major regions of the United States, with the South exhibiting an 85% increase in constant dollars allocated to agricultural economics research from 1970 to 1979

Joseph Havlicek, Jr., is a professor, Department of Agricultural Economics and Department of Statistics, Virginia Polytechnic Institute and State University.

and a 53% increase in constant dollars allocated to other agricultural research. In the Northeast, the constant dollars allocated to agricultural economics research increased about 41%, while the constant dollars allocated to other agricultural research declined 3%. In the West, constant dollars for agricultural economics research increased 45% and constant dollar funds for other agricultural research increased 28%. The North Central Region exhibited only a 12% increase in constant dollar funds for agricultural economics research and a 20% increase in constant dollars for other agricultural research.

The number of scientist years (SY) and funding per scientist year are other measures which provide some information about how agricultural economics research compares with other agricultural research. The 1979 data on scientist years is preliminary and questionable, so the analysis of the data for the twenty-three RPAs was performed for the 1970–78 period rather than the 1970–79 period. In the SAES the number of scientist years devoted to agricultural economics research increased 22%, and the number allocated to other agricultural research increased 12%. In the USDA the increases in scientist years are considerably less, with agricultural economics research exhibiting a 3% increase and other agricultural research showing only a 1% increase. In the SAES the constant dollars allocated per scientist year in agricultural economics research increased 7% from 1970 to 1978 and increased 18% in other agricultural research. In the USDA the constant dollars per scientist year increased 45% in agricultural economics research and 15% in other agricultural research. Hence, there have been greater increases in SYs in the SAES, but the constant dollar funds per SY have increased considerably more in the USDA than in the SAES.

One cannot help but comment on the fact that in the survey conducted by Farrell and Stanton not one department chairman or administrator gave rural development a high-priority rating. It is doubtful that this result implies that those responding do not feel that important economic problems exist in the rural development area. Rural development research has been difficult to assess, and the usefulness of some past research in this area has been questionable. One of the difficulties with assessing rural development research is that the output of the research is difficult even to identify, and little headway has been made in measuring it.

Finally, there seem to be some severe difficulties with the general public, and these difficulties are likely to get worse. Even though the figures discussed by Farrell and Stanton and myself suggest that agricultural economics research has fared no worse than other agricultural research, the increases are not exactly spectacular, given that they encompass ten funding years. The increases are indeed modest. Science and research have lost credibility with the general public as well as the public's support. It may be a characteristic of the time that it is bad to be an agricultural scientist, even worse to be a social scientist, and worst of all to be a social scientist in agriculture. Part of the difficulties with the general public may be due to the inadequate job we have done in informing the general public about what researchers do and the benefits of their activities. Even in cases where attempts have been made to communicate the benefits of research activities, the focus has been on producers and legislators and not on consumers, who are the ultimate beneficiaries of agricultural research. However, the problem may be more serious than communication. Agricultural economists may not be dealing with the important and relevant economic and policy issues of the general public. This, of course, is more difficult to deal with than just improvement of communication. But both of these difficulties with the general public offer challenges and opportunities for the 1980s.

Funding for Agricultural Economics: Discussion

W. D. Toussaint

I would like to commend Stanton and Farrell for the work they did in compiling the data for their paper and for supplying us with their analysis and recommendations. I will comment on several points relative to both data and recommendations.

Their data seem to show an increasing share of the public sector research dollar going to agricultural economics research in the last decade. This may be true. It may be, however, a function of the CRIS system and how research projects are coded. They retrieved their data on Field of Science 2630 (economics). I found earlier that a very high proportion of the 2630 research in some southern states is in other departments (Toussaint, p. 24). We would have to know what the trend has been in reporting 2630 in other departments, to have a better feel for this. Further, I found (p. 25) that the share of state agricultural experiment station funds expended in agricultural economics departments generally fell in the southern states from 1967–68 to 1977–78, which seems a little at odds with the findings of Farrell and Stanton. Funding for extension activities in these same states also seemed to decline slightly.

Farrell and Stanton show that more department heads indicated an increase than indicated a decrease in agricultural economics funding as a proportion of college budgets. I suspect this is due primarily to the teaching component. If the lag in reallocating teaching funds were not so long, I suspect that we would have an even larger share of university budgets today. This agrees with the authors' point that research may have subsidized teaching during this period of rapidly increasing enrollments. Throughout the nation we have had greatly increased enrollments in business and economics. As a consequence, teaching loads have become much larger in these areas.

The author is a professor of economics and business at North Carolina State University.

Why might our share of research funding have dropped, if it has? I believe that agricultural economics research has declined in value in the eyes of experiment station directors in recent years. Real funding for research has decreased, and, as budgets are squeezed, directors look for projects with visibility and high, immediate payoff. We do not always rate well on these scores. As experiment stations rely more on nonpublic funding sources, they must have research that has high payoff to their commodity groups. Ruttan (p. 12) says:

> . . . both consumers and producers tend to support those agricultural research activities with which they have the most direct contact. The relatively sophisticated arguments based on relative shifts in demand and supply functions and on changes in producers' and consumers' surplus have apparently been difficult to translate into a language that generates political support from organized producers or consumers.

Rural development research has hurt us in many eyes, and this is not all our fault. Remember that the money was almost forced upon us and, in many cases, only replaced funds for other projects. Many of us were not ready for this kind of research; we did not always have all the skills. As a consequence, much of our work was not particularly good. Other research was not easy to evaluate.

Farrell and Stanton ask why we should have to get new funding by attaching riders to physical science requests. It may be a little difficult for us to swallow, but this may continue to be a good strategy. Riding with physical science requests and participation in interdisciplinary research may be two of our best strategies for gaining visibility and funding.

I must admit to being less than hopeful about gains to be achieved by our profession as a group, spelling out and advertising our needs and our contributions. Previous attempts to do this often have ended looking like the usual report put together by a committee. For example, *Animal Agriculture: Research to*

Strategies for Dealing with World Hunger
(D. Woods Thomas, Purdue University, Presiding)

Strategies for Dealing with World Hunger: Post-World War II Policies

Wayne D. Rasmussen and Jane M. Porter

Farmers, farm politicians, and agricultural economists have something in common. Their products, whether food, laws, or theories, are dependent upon the weather. This is obvious in the case of farmers. Their product depends upon many things, including the state of the arts in agriculture in a particular region or nation, the availability of credit, the costs of energy and fertilizer, and so on, yet the overriding variable, with only limited exceptions, is weather. If the monsoons are favorable in India, the frost holds off in the Soviet Union, and timely rainfall comes to Argentina, Australia, Canada, and the United States, there is a world surplus of grain. Conversely, if weather conditions are unfavorable in these areas, the world faces shortages.

If there are surpluses, politicians face the problem of establishing programs that will assure farmers reasonable incomes, reduce production, remove surpluses from the market and dispose of them, and bring about the retention of the politicians in office, all at little cost to the taxpayer. If there are shortages, the problems are still complex, with questions of export embargoes, high consumer prices, the maintenance of farm income, the stimulation of increased production that will ease shortages and not lead to surpluses, and the retention of the politicians in office, all at little cost to the taxpayer.

The relationships between the weather and the agricultural economists is not so clear unless we accept and keep in mind the proposition that weather is the most important of all the variables in determining whether we have surpluses or shortages, or, indeed, whether we reach that golden mean where production equals effective demand. Thus, over the past thirty-five years since World War II, the dominant economic theory at any given moment has been, when surpluses were at hand, they threatened to drag the economy down to disaster; or, if there were shortages, the world was threatened with starvation and wars over food supplies. Oddly enough, weather conditions, with their resulting surpluses or shortages, led some economists to make rather short and fast turnabouts. For the most part, though, it appears that economists belonging to two different schools of thought have taken turns explaining their theories and making their forecasts as world weather has changed.

Because there is little we can do to bring about major changes in the weather, at least with present technologies, we will accept it as given, so far as this paper is concerned. Our purpose will be, then, to look at the relationships between agricultural policies and programs as they relate to world food supply and to look at economic theories and forecasts because they have an effect on policies and programs. The programs and policies of many nations and of international organizations affect the world food supply, but our paper is limited to those of the United States, with some attention to the relationships of the United States to other nations and to international organizations.

World War II ended with American farmers reaching the highest levels of food production ever in 1945 and 1946, yet world shortages threatened many people with starvation. Vocal American consumers, because of high incomes and rationing and shortages during the war, were calling for the removal of all

Wayne D. Rasmussen and Jane M. Porter are historians in the National Economics Division, Economic Research Service, U. S. Department of Agriculture.

restrictions on consumption. Producers felt that price controls had limited their possible profits and also were urging the end of controls (Wilcox).

The federal government had been discussing postwar relief in Europe and other parts of the world almost from the time of Pearl Harbor. By the fall of 1943, various proposals and discussions had led to an agreement to establish the United Nations Relief and Rehabilitation Administration. The agreement was signed on 9 November 1943, by the representatives of forty-four nations. The Department of Agriculture played an important part in establishing and staffing UNRRA.

UNRRA was to be a temporary organization that would end with the completion of its mission. Even before it was established, a permanent international organization to deal with food and agricultural problems was being discussed, with an international conference held at Hot Springs, Virginia, in May and June of 1943. In July 1945, the Food and Agriculture Organization of the United Nations came into being. The Department of Agriculture had been the continuing force behind the establishment of FAO and contributed heavily to its staffing.

By the time the postwar food crisis hit the world, there were international organizations and sheaves of plans in the Department of Agriculture for dealing with it. However, there was not enough food to go around. The tremendous grain reserves had been turned into meat, dairy, and poultry products to feed our armed forces, allies, and civilians. During the last months of the war, some policy makers had determined to leave a bare pantry, fearing that surpluses would soon return, as they had following World War I. The policy makers of various agencies and allied countries distrusted one another, each thinking that the other was hoarding large stockpiles of food. However, the stockpiles proved to be imaginary. The crisis was so severe that President Truman announced a series of emergency measures and appointed a Famine Emergency Committee and a National Famine Emergency Council to provide leadership and obtain public support for the effort. Later a Citizens grain. From 1945 to 1948, the United States supplied more food to the hungry abroad than any other nation has ever done before or since. The question still remains whether or not our efforts were adequate. As might be expected, evaluations about what should have been done and what was done vary. One well-known economist, Theodore W. Schultz, said in 1946: "The United States has on several major counts—seriously, in my judgment—mismanaged its food supplies. . . . in the United States the average person's consumption has jumped to the unprecedentedly high level of thirty-three hundred calories per day. . . . we should return to our wartime levels of food consumption, in order to stand by the European and Oriental peoples during this world-wide food crisis" (Moore, Schultz, Tolley, pp. 22–23).

The postwar planning effort in the U.S. Department of Agriculture (USDA) was led mainly by some of the Department's outstanding economists, including Howard Tolley, Leslie Wheeler, Roy Kimmel, Raymond C. Smith, Louis Bean, and Mordecai Ezekiel.

Soon after the outbreak of the war in Europe and long before Pearl Harbor, President Roosevelt had ordered each cabinet officer to produce a set of postwar projects. One objective of this exercise was to be prepared for a postwar economic slump. The economists in the USDA saw this as the opportunity to make some badly needed long-term adjustments in the American agricultural plant. Plans were to be prepared for each major region of the country. The principal concerns were (*a*) an adequate income and level of living for farm families; (*b*) care of the soil, with consideration for the differences in soils and climates to insure a permanently productive agriculture; and (*c*) production of those commodities demanded by the market with abundance but no large surpluses.

The postwar plans of the economists in the USDA, in retrospect, seem sound to us. Many of their objectives have been achieved, with or without planning. But when the content of these plans reached the ears of the public, the wrath of certain influential politicians descended on the department. The responsible

passed the Foreign Assistance Act, the authority for the Marshall Plan to revive Western Europe. Substantial shipments of food were made under the plan. Amid all of the crisis activities a few economists began taking a longer look into the future. Pearson and Harper, writing in the closing months of the war, held that food shortages were caused by demand for higher quality food and a worldwide shortage of arable land. They offered no hope of a rapid worldwide increase in food availability and postulated that if a projected rapid increase in population materialized, diets would have to be downgraded if famine was to be avoided in some parts of the world. Albert Viton, chairman of the International Emergency Food Council, told the Farm Economics Association in 1947 that a new economic philosophy had emerged in the postwar period. This philosophy of "full employment" would lead to rapid economic growth, increased demand for higher-quality food, a period of relative prosperity for agriculture and rapidly increasing agricultural output in both the developed and less developed areas. He cautioned, however, that there would be regional maladjustments and that the United States might see the return of surpluses by 1949 or 1950 (Pearson and Harper).

The first worldwide census effort, made under the auspices of the United Nations in 1950, showed that a population explosion was in progress. The world, by this time sorely divided by the cold war, faced an indefinite period of food imbalances and insecurity. The traditional bread basket of Europe was behind the iron curtain. The rice bowl of southeast Asia was torn by fratricidal warfare. A new group of economists at the USDA began to see long-term opportunities for American agriculture in foreign markets.

The message went out to American farmers: "Expect to fill a fifth plate at the dinner table." That is, agricultural exports were expected to take about one-fifth of our production. Farmers could maintain and even expand production without fear of price-depressing surpluses.

The euphoria was short-lived. With the end of the Marshall Plan and the Korean War, surpluses returned in the United States. Although there had been proposals for the establishment of international buffer stocks and reserves of food under consideration since 1937 and the subject had generated a good deal of heat at the Hot Springs Conference, the economists, here and abroad, could only agree to disagree. Even the International Wheat Agreement ratified in 1949 made no provision for food reserves.

The Agricultural Act of 1949 provided the first authority for donating surplus agricultural commodities abroad through United States voluntary relief organizations. A significant step in technical assistance also came in 1949 when President Harry Truman, as Point 4 of his foreign policy, stated that we must make our scientific and industrial advances available to underdeveloped areas. Special legislation provided for food donations to help the Greeks and Turks in their fight to repel communist take-over attempts in 1952 and to relieve famine in Pakistan in 1953 (Matusow). In 1953 the legislative hoppers were filled with proposals to get rid of agricultural surpluses by shipping them out of the country by one means or another. The prospect of large-scale export dumping by the United States alarmed the other wheat exporting countries and some major developed importing countries. The 1953 session of the FAO Conference, after considerable discussion, directed its Committee on Commodity Problems to study the means and principles of international disposal of surplus agricultural commodities. The Committee met in Washington during February and March of 1954. It produced a set of recommended principles to be followed in the disposal of agricultural surpluses. From the language used in this document and the language which became U.S. law in the Agricultural Trade Development and Assistance Act, better known as P.L. 480, it is apparent that there was very close communication between the Committee on Commodity Problems and those who drafted P.L. 480. Mordecai Ezekiel reportedly drafted the "Principles" recommended by FAO (United Nations 1954).

In spite of the language similarities, however, the Agricultural Trade Development and Assistance Act did not result from FAO proposals. There were a number of surplus-disposal bills introduced in 1953, as noted previously, and there were a number of committees studying them. In a maze of bureaucratic wrangling, the interdepartmental committee on the surplus, established by President Dwight Eisenhower and chaired by Undersecretary of Agriculture True D. Morse, finally agreed on an administration bill. It was a compromise between the proposals of the American Farm Bureau Federation and the desires

of several federal agencies to control the new program. The bill moved quickly through the Congress and was approved by the president on 10 July 1954 (Peterson, pp. 36–41). The law has remained a cornerstone of American programs relating to world hunger.

Public Law 480, as enacted in 1954, had four titles: Title I provided for sales of surplus agricultural commodities for foreign currencies which could not be converted into U.S. dollars. The disposal of these currencies was to be arranged through agreement between the receiving country and the U.S. State Department, but a certain percentage was to be reserved for U.S. uses such as financing our embassies. Title II provided for donations of surplus commodities for disaster relief through U.S. voluntary organizations of friendly governments. Some limited donations could be made for economic development. Title III provided for the barter of surplus agricultural commodities for strategic and critical materials to be added to U.S. stockpiles of these materials. Title IV provided for long-term credit to finance dollar sales of agricultural commodities. Titles I and II cover the P.L. 480 functions that will be discussed in this paper.

Mordecai Ezekiel and Rodan Rosenstein were sent to India by the FAO to monitor the first use of surplus food. This landmark research provided the detailed economic rationale for the use of surpluses to help finance economic development. The study concluded that surpluses to be used for development should be tied to an equal amount of other resources and committed to designated projects. When surpluses are used to put unemployed men to work and they produce something that adds to the capital goods of the country, development is taking place (Ezekiel; Iowa 1962, pp. 278–301; UNFAO 1955).

Although forty-eight countries accepted the principles set forth by the FAO on the disposal of agricultural surpluses, and these were reaffirmed when the Wheat Utilization Committee was established in 1959, they were more frequently honored in the breach than in the observance at least up until 1965.

The terms of surplus agreements under P.L. 480 in the late 1950s and early 1960s put more emphasis on protecting and maintaining "usual" commercial imports than on uses for development or preventing the concessional sales and grants from acting as disincentives to farmers in the recipient country. The Subcommittee on Surplus Disposal of the Committee on Commodity Problems of the FAO continued to monitor surplus disposal. Studies in Japan and Pakistan showed that the program had worked along recommended lines in Japan, but that in Pakistan and some other countries it had only supported increased consumption. Cheap food policies in many Latin American and Asian countries tended to stifle domestic agricultural production. Sudden cut-offs of commodities after countries had become dependent on them carried serious threats to vulnerable populations. In 1959, for example, the cut-off of supplies of dry skim milk was damaging to child-feeding programs in many countries (Davis, Shefrin, Iowa 1962).

The FAO objectives of food for development proved difficult to implement. The agencies with capital to disburse, such as the World Bank and the U.S. International Cooperation Administration, favored large capital-intensive, show-piece projects. Food-for-work inputs to such projects were a nuisance. Small labor-intensive projects cost too much to administer. Furthermore, the voluntary agencies who disbursed a large part of the food-aid grants were oriented toward charitable, disaster relief types of operations and protested against the requirements that their deprived clientele be forced to work for food donated by the American people. Nevertheless, a few highly successful food-for-work projects were implemented during the 1950s. For example, Elmer Starch conceived and carried out a pioneering program of reforestation and small-scale irrigation in Tunisia.

During the late 1950s much of the surplus food sold for local currencies went to technically advanced but food-deficit countries: Japan, Israel, Taiwan, and Korea. Each was densely populated, with limited tillable land. Each of these countries concurrently invested in developing its own agriculture, perhaps not with the objective of becoming self-sufficient in food, but of developing a highly productive specialized agriculture. Each graduated from food aid dependency during the 1960s and has become a sometime-competitor, sometime-customer for U.S. agriculture. Surplus disposal had justified some of the original theoretical expectations but had opened up a whole series of new problems (DeBlois).

India was an example of food aid results at the other extreme. By 1960 the accumulation of blocked currencies resulting from P.L. 480 sales was so large that it was threatening the

financial structures of the country (Purvis). Surpluses were being produced in the exporting countries, particularly the United States, faster than they could be channeled into consumption, regardless of the mode of payment or nonpayment. The original AAA of the U.S. program had been designed to control production, but through political and economic pressures over the years it had put a premium on efficiency resulting in increasing yields and increased production. World prices of commodities were in a continuous downward trend from the early 1950s. This was the principal item on the agenda for the meeting of the Economic and Social Council in the summer of 1959 (United Nations 1959). Obviously the large volume of U.S. exports, both commercial and concessional, had influenced the trend of world prices. Thus, our exports had become a disincentive to the expansion of production. At any rate, it was necessary to negotiate in 1959 a P.L. 480 agreement of record-breaking magnitude with India to fill her food grains deficit during the ensuing four years. The morocco-bound volumes of a landmark study entitled *India's Food Crisis and Steps to Meet It* were left to molder on the shelves of the library of the Ministry of Agriculture (Ford Foundation). This study had been funded by the Ford Foundation and led to its rural development program in India which, in the short run, did little to increase food availability. By 1965, when the monsoon failed, India was already a basket case.

But by 1965 the economists had provided the politicians with a whole new basket full of economic theories and statistical data. Galbraith, having published *American Capitalism; the Concept of Countervailing Power* (1956), *The Affluent Society* (1958), and *Economic Development in Perspective* (1962) and having also served as U.S. ambassador to India 1961–63, was advising and criticizing the administration in Washington from his dais at Harvard. Walter W. Rostow, having produced *The Stages of Economic Growth, a Non-Communist Manifesto*, was firmly entrenched in the inner policy making councils of the State Department. Gunnar Myrdal assumed the mantle of Thor with publications like *Rich Lands and Poor*, *The Road to World Prosperity*, and *Challenge to Affluence*, and was writing the *Asian Drama, an Inquiry into the Poverty of Nations* in 1968.

The period 1959–65 witnessed an upsurge in publications on economic development, agricultural development, and food and population problems. The views of Galbraith and Rostow dominated a study on foreign aid policies produced by the Maxwell Graduate School of Citizenship and Public Affairs for the Senate Foreign Relations Committee in 1959 (U.S. Congress, Senate, Foreign Relations Comm.). Thus study suggested that food surpluses be committed over a period of years to enable countries to use their limited financial resources to push industrial development. It stated that many of the densely populated less developed countries (LDCs) could never hope that agriculture could supply an adequate level of living for their populations. Its policy repercussions are evident in the aforementioned P.L. 480 agreement with India and in India's second five-year plan which stressed industrial development.

Bruce F. Johnston and John W. Mellor began the counterattack with "The Nature of Agriculture's Contribution to Economic Development" published by the Stanford Food Research Institute in November 1960. A year later in the *American Economic Review*, they published "The Role of Agriculture in Economic Development." Johnson and Mellor postulated three phases in agricultural development:

Phase I: Providing the preconditions for agricultural development.

Phase II: The use of low-capital, labor-intensive technology results in increasing yields per acre and overall production.

Phase III: Reinvestment of profits in the agricultural sector leads to more capital-intensive technologies, reduced labor inputs and rapidly rising productivity.

The authors said that due to the availability of cheap land and the scarcity of labor, this development path was not followed by the United States. Japan and Taiwan were cited as good modern examples.

A session at the 1960 annual meeting of the Farm Economic Association featured a paper by Theodore W. Schultz on the "Value of U.S. Farm Surpluses to Underdeveloped Countries." Max Myers, at another session, said that public support for the use of agricultural surpluses to meet the food needs of food-deficit countries was a dynamic movement in both the producing countries and the deficit countries. This was evident in public support for "Food for Peace" and FAO's "Freedom from Hunger" campaign launched in 1960. Don Paarlberg had left the Depart-

ment of Agriculture late in 1958 to head a Food for Peace office in the White House.

A new thrust of research on world food problems began early in 1961 in the USDA. The initial product, entitled *The World Food Deficit, A First Approximation,* was published in March 1961. This was followed in October 1961 by *The World Food Budget 1962 and 1966.* These studies led to a contract (called a PASA) with the Agency for International Development for the Economic Research Service to carry out a study of agricultural development in twenty-six developing nations (USDA 1965). A study group headed by James P. Cavin was established by Willard Cochrane in the Economic Research Group in 1961. Its widely circulated report, issued in March 1963, stressed the importance of agriculture to development.

Meanwhile, a young economist in the USDA was writing two monographs, *Man, Land and Food, Looking Ahead at World Food Needs* followed by *Increasing World Food Output: Problems and Prospects.* Lester R. Brown, the author, acknowledges in the preface to the latter volume that he had attempted to apply Rostow's concepts of economic growth to the agricultural sector, substituting yield per acre for income per person in applying the takeoff concept. Politically, it was a coup, as Rostow reciprocated by acknowledging the role of agriculture in economic growth. Secretary of Agriculture Orville Freeman's objective of reestablishing the role of agriculture, and particularly of the USDA in the foreign aid program was advanced. Funding from AID for continuing USDA research on agricultural development was assured and the participation of action agencies such as the Forest Service, the Soil Conservation Service, the Rural Electrification Administration, the Agriculture Stabilization and Conservation Service, and the Agricultural Research Service in foreign agricultural development projects was gradually increased. A new agency, the International Agricultural Development Service, was established to coordinate USDA participation.

Research on agricultural development was also expanding in the land grant colleges and other institutions. A notable conference, which brought together professionals from many disciplines to discuss the role of food and agriculture, was held at Iowa State University in February 1962 (Iowa 1962). A World Food Congress was held in Washington, D.C., 14–18 June 1963. It was jointly sponsored by the FAO Freedom from Hunger Campaign, the U.S. Agency for International Development and the USDA. The list of participants read like an international Who's Who. Arnold Toynbee and Orville L. Freeman expressed opposing views on the future prospects of the world's ability to feed itself. Freeman, the optimist, said that the export of U.S. technology would produce a worldwide explosion in yields (Toynbee, Freeman 1963).

The imaginative use of U.S. surplus stocks of grains to "buy time" while development programs increased yields in food-deficit countries was also advocated by the Freeman administration. When the food crisis developed in India in 1965–67, it was thoroughly dramatized both in the United States and the rest of the world as a foretaste of things to come if the imbalances between food supplies and population growth were not corrected. A galaxy of specialists from many disciplines was sent by the USDA to India to help revamp her agricultural development program. Freeman took advantage of the desperate need for U.S. grains to prod the Indian government into implementing the recommendations of USDA specialists. Under the pressure of the Indian food crisis, amendments to Public Law 480 were pushed through the U.S. Congress. These amendments redirected the program from surplus disposal to use as a tool in promoting agricultural development in food-deficit countries (Freeman 1968).

In his "Message on Food for Freedom," 10 February 1966, President Johnson directed his Science Advisory Committee to study the world food problem and recommend ways and means of increasing the world's food supply. The panel appointed by the committee studied the problem for a year with the full cooperation of all of the applicable disciplines and institutions. The report, published in May 1967, concluded that hunger and malnutrition were not primary diseases of the last half of the twentieth century but were symptoms of a deeper malady, lagging economic development on three continents where nearly two-thirds of the world's people live (President's Science Advisory Committee). Abel and Rojko, in the USDA, asserted that over the long pull, U.S. food production would be able to meet the market demand for food and that this should have primacy in USDA policy considerations. New, high-yielding varieties of wheat and rice spread rapidly in the food-

deficit regions, normal weather returned, and surpluses began to accumulate again in the United States. Public concern over the food crisis abated (Dalrymple).

The commitment of the Johnson-Freeman administration to agricultural development as the means of solving the world food problem continued for the duration of their incumbency. In 1968 Freeman urged major attention to international food development in his book *World Without Hunger*, but by this time the country was immersed in the Vietnam War. Conflict over the Vietnam War seemed to turn American public opinion inward. Foreign aid became equated in the minds of the public and the politicians with U.S. dollar imperialism or worse things. As long as the Vietnam War continued, the U.S. Congress continued to be hostile to foreign aid. Between 1968 and 1972 the question of the future of foreign aid was studied by a number of prestigious groups, including the American Assembly of Columbia University; a task force of the National Association of State Universities and Land Grant Colleges; the National Planning Association; The Committee for Economic Development; the World Bank; joint report by Clifford M. Hardin, Secretary of Agriculture, and John A. Hannah, Administrator of AID to President Nixon (Hannah and Hardin); and a presidential Task Force on International Development (known as the Peterson Report). The recommendations of these study groups were diverse, but there was a common thread of emphasis on agricultural development. The United States should increase its foreign aid expenditures; more emphasis should be placed on agriculture and population programs; technical assistance and development lending should be funded on a multiyear basis; debt burdens of the LDCs should be eased; and trade concessions should be made for them. Despite this support, aid authorizations and appropriations were regularly shaved to the bone and even then were barely passed by the Congress.

The early 1970s saw American food policy influenced by devaluations of the dollar, the "great Russian grain robbery," "embargoes" on wheat and soybeans, the unprecedented increases in agricultural and food prices, the organization of OPEC, and the escalation of petroleum prices (Breimyer, pp. 3–5). Close on the heels of these developments, drought in the Sahael brought on a new food crisis. There arose an outcry that the United States had no food policy, domestic or foreign. Meanwhile, Secretary of Agriculture Earl L. Butz was saying that increased production would solve our problems and was urging farmers to plant "from fence row to fence row."

The U.S. Congress began to change its attitude toward foreign aid programs beginning in 1974. AID was directed to address its programs to meeting the basic human needs of the poorest countries. The dilemma in food is that those who do not have enough do not have the money to pay for it and those who produce more than they need cannot afford to give it away.

The dilemma was stressed at the meeting of the World Food Conference in Rome in 1974. A number of recommendations were made by the conference which may have had some effect upon national policies (U.S. Congress 1975). However, the recommendations would, for the most part, still be appropriate today. One result of the conference of great value to economic analysis was that it was the immediate impetus for the establishment of the International Food Policy Research Institute (IFPRI, pp. 3–5).

The World Hunger Commission promised a new assessment of current and future food problems when it began work in 1978. Yet, regardless of the findings and recommendations of the Commission, the United States probably will continue to be influenced by political realities, recommendations of agricultural economists, and the weather in making or changing its policies on world food supplies. We do know that total food production by developing countries rose steadily throughout the seventies but varied greatly by region (USDA 1980).

Secretary of Agriculture John R. Block has stated repeatedly that increasing farm exports is one of his major goals. He emphasizes commercial exports, but does not rule out shipments for disaster relief. There are problems associated with maintaining or increasing exports. The United States has become a residual supplier, which means that the prices farmers receive for exports may vary markedly from year to year. We may have surpluses or shortages from one year to the next, depending in large part upon weather conditions throughout the world. Maintaining high productivity for export may be reducing soil fertility and making the soil more subject to erosion. It has been charged that meeting world demand increases consumer prices in the United States (Cochrane p. 274, O'Brien).

On the other hand, we may be moving into a

new state of equilibrium, as John Lee has suggested, with production and effective demand being in relative balance. But Don Paarlberg leaves us with a challenge: "Enough food? Yes, if we act wisely. If there is scarcity it will be because, with unwise policies, we have brought it upon ourselves."

Reflections on the Presidential Commission on World Hunger

Walter P. Falcon

In September 1978, then President Jimmy Carter appointed a twenty-member Commission on World Hunger. The commission's mandate was to identify the basic causes of hunger at home and abroad, to assess programs and policies affecting hunger, and to recommend (and publicize) specific actions to create a coherent national policy. The group had bipartisan political support, and four of its members were from Congress.[1] Unlike previous commissions of food and agriculture, however, representation from economists and agricultural scientists was quite limited. Although this was both a strength and weakness of the commission, it had the unfortunate consequence of involving fewer professional groups than might have been desirable. In part, therefore, this essay is an after-the-fact (and slightly expurgated) report to agricultural economists on "what happened."

Because the entire commission *Report* is readily available, I will not summarize its findings, although a number of recommendations from the *Report* are highlighted.[2] The many changes (including the presidency) that have occurred since the commission reported formally in March 1980 suggest instead the need for a critical appraisal of the *Report* and for comments on possible next steps for the United States in the field of hunger alleviation.

Walter P. Falcon is Farnsworth Professor of International Agricultural Policy and Director, Food Research Institute, Stanford University. From 1978–80 he served as a commissioner on the Presidential Commission on World Hunger.

The helpful comments of Bruce Johnston, Scott Pearson, and Anne Peck are gratefully acknowledged. Variations on the themes of this essay were given previously at Macalester, Purdue, and Michigan State Universities.

[1] The commissioners included Sol Linowitz (chairman), Jean Mayer and Steven Muller (vice chairmen), Norman Borlaug, David Brooks, Harry Chapin, John Denver, Robert Dole, Walter Falcon, Orville Freeman, Benjamin Gilman, Patrick Leahy, Bess Myerson, Richard Nolan, Howard Schneider, Adele Simmons, Raymond Singletary, Jr., Eugene Stockwell, Clifton Wharton, Jr., and Thomas Wyman.

[2] The Presidential Commission on World Hunger no longer maintains an office; however, copies of the *Report* are for sale by the Superintendent of Documents, Government Printing Office, Washington, D.C. 20402. (Stock No. 041-002-00015-8, $6.00 per copy.)

Dimensions of the Hunger Problem

Perhaps the strongest aspect of the commission's *Report* is its description of global hunger. Unlike other documents, for example, the recent National Academy of Sciences study that emphasized production problems and technical solutions, the *Report* is much broader in its scope and outlook. Much of the *Report*'s extensive, and often moving, description of hunger can be captured in five words: Asia, children, calories, chronic, and poverty.

In setting forth the quantitative dimensions of hunger, the commission began implicitly from the framework suggested by Reutlinger and Selowsky. The incidence of hunger is estimated with this methodology from consumption-income relationships. To the extent that personal needs, average daily requirements, income distributions, or Engel coefficients are misspecified, the resulting conclusions on the number of hungry people are also affected. Using different assumptions, Eberstadt, for example, concludes that hunger affects perhaps only 100 million people, with the most severe problems concentrated in Africa. By contrast, however, the commission concluded that between 500 million and 1 billion people suffer from moderate to severe protein-calorie malnutrition (PCM). Large and disquieting as this range may be, it probably has little bearing on America's attitude or its capacity to help with solutions. Hence, there seems little need, at least in this essay, to fine-tune estimates, as further refinement would have little bearing on public policy.

Policy direction, however, does depend importantly on the five words mentioned previously. Of the approximately 800 million people thought to be suffering from moderate to severe undernutrition, about two-thirds are in Asia. Indeed, on a global basis, about 70% of all hunger is in nine countries, (India, Pakistan, Bangladesh, Indonesia, Philippines,

Kampuchea, Zaire, Ethiopia, and Brazil). Any domestic or international proposals aimed at ending world hunger must deal fundamentally with these nations. The difficult formal relationships between the United States and a number of these countries underscore immediately the political dimensions of the hunger problem and the limits to which the United States can now help with a solution—assuming that it wishes to do so.

Irrespective of the exact total of hunger-affected individuals, there are special groups within populations where PCM incidence is the highest. Weanling children from ages one to four present the most serious problem. Whereas cereal-based diets are largely adequate for adults, the relatively low density of these foods means that small children literally cannot eat enough of them to be nourished adequately. In addition, the interactions among undernutrition, poor water quality, and other public health components are especially critical among the young. These interactions are one reason, for example, infant mortality rates in Africa are more than six times the level of developed countries. As the *Report* correctly notes, unless infant mortality rates can be reduced, it is unlikely that birth rates can be brought down a significant degree.

Pregnant and lactating women are also given special attention. The extra strains of childbearing place these groups seriously at risk with respect to nutrition. In addition, a generational effect deserves specific mention. There is almost no existing scientific evidence to suggest physiological relationships between mental retardation and undernutrition. An exception to this statement is that undernourished mothers fail to carry fetuses to full term much more frequently, and among premature births, the incidence of mental and other handicaps is substantially higher. On the other hand, there are strong correlations among moderate or severe undernutrition in children, learning motivation, and behavioral patterns.

One important implication for economists of the "children and mothers" component of the problem concerns household allocations of food. Many analysts typically think of household consumption as the central unit of observation. Unfortunately—since the issue presents severe research and intervention difficulties—how food is allocated within families may be at the very core of the hunger program in many situations.

A third component of the hunger problem involves calories. Although this point is increasingly recognized, it also is true that for twenty years many in the nutrition profession had the world pointed in the wrong direction. Indeed, survey work by the commission indicates that many Americans still believe that protein is the most severely limiting nutritional element. Except in a few localized regions, however, the overwhelming PCM problem is simply getting enough calories. Widespread evidence suggests that groups with sufficient energy resources have typically also found ways to provide the necessary protein complement.

A fourth element in defining global hunger concerns its chronic dimension. Partly as a result of modern communications, the specters of war- or drought-induced famines are well known to most families in the United States. The coverage of events such as the Sahel drought, the Kampuchean and Somalian disasters, or the boat people from Viet Nam are almost daily occurrences on television. Horrible as these situations are, they simply are not the dominant hunger problem in terms of numbers. Clearly, the intensity of the PCM problem is worse in famine areas, but it is also true that famines occur much less frequently or severely than even fifty years ago. In addition, global support generally can be mobilized much more readily for disasters than for hunger of a chronic nature. It is easy enough for responsible persons to grasp the hunger complications caused by drought. It is almost impossible, however, for anyone to visualize one-sixth of the people on earth suffering from moderate to severe continuing undernutrition.

Of all the definitional components, however, the *Report* comes down most firmly on the issue of poverty. There may be isolated instances where people are undernourished because they are not making good use of local food resources in terms of either total quantity or composition. However, the overwhelming reason people are hungry is not because they are ignorant or uneducated but rather because they are poor.[3] The recognition that poverty, and not food production, is the major problem is an important step forward, especially for the agriculturalists (and others) who may believe the contrary. Yet the implications are sobering

[3] An exception to this statement involves infant-feeding practices, where educational efforts can sometimes make an important difference.

on two counts. First, a question is immediately raised as to whether those "who are poor, need not be hungry as well" (*Report*, p. 40). In the United States, largely through the Food Stamp Program, it has been possible to separate these two afflictions.[4] Given both the resource costs and the administrative problems encountered in America, however, can or should similar programs be replicated in low income nations? Second, if it is impossible to separate hunger from poverty, what can outsiders—even well-meaning ones—do to help attack the fundamental problems of income levels and distribution? This latter issue was at the base of many of the commission's deliberations. Given the wide range of political views represented on the commission and its staff, many of these sessions exhibited heat if not light.

Vigorous debate notwithstanding, the commission came eventually to a shared perception of the major causes of global hunger and also to some of the needed solutions that followed directly from problem definition. For example, it agreed that improvements in nutrition and infant mortality were a prior condition to solving population-growth problems and not vice versa. Similarly, it concluded that increased food production was a necessary, but not sufficient, condition for solving hunger. But in other areas, mainly associated with methods for alleviating poverty, the *Report* contains curious contradictions, both in the main text and in the numerous dissenting comments.

Hunger Alleviation within the World Food Economy of the 1980s

Of the numerous operational recommendations in the *Report,* issues surrounding trade, debt, and world food security occupy a prominent position. Some of the reasons for this focus are clear. The rise in oil prices had badly hurt a number of low income, food-importing countries that had been caught in a double balance-of-payments bind during the 1970s. Agricultural trade, including food aid, were also fields in which the United States was dominant. Somewhat ironically, however, the linkages among agricultural trade, poverty, and hunger are among the weakest analytically in the entire *Report,* and a generally inadequate case is made for linking hunger problems with other developments in the world food economy. Of fundamental importance is the fact that "hungry people" are not the central element in the world economy for food products. Moreover, the global environmental is probably becoming more, rather than less, difficult for solving hunger problems.

The 1970s represented a transition in the world food situation. This change consisted of many components, only two of which will be highlighted here.[5] One fundamental element centers around the demand for meat. Between 1960 and 1980, the amount of grain consumed globally by animals doubled, from 20% to 40% of total cereal production. In 1980, for example, more grain was fed to animals than consumed by the 1.4 billion people living in countries with per capita annual incomes of less than $250. Although the decade of the 1970s still saw many people mired in poverty, it also saw numerous groups and nations reach a state of affluence that involved greatly increased demands for meat. Such diverse nations as Nigeria, Taiwan, China, South Korea, and Mexico became major entrants into world feed grain markets.

The second major element of the 1970s, about which there is still great debate, involves events within the United States. At the present time and at present prices, there appears little excess capacity within American agriculture. Moreover, much of the recently utilized agricultural capacity has already been "exported." In 1970/71, the United States shipped 41 million tons of grain, which represented 37% of global cereal trade. By 1980, the export share had risen to 56% and to 118 million tons. With already large exports and with some evidence of stagnating productivity within agriculture, the next decade surely will see a reduction in the rate of export growth from North America. The decade will probably also see rising real prices of grain globally and increased price variability as well.[6]

[4] Section 5 of the *Report* deals specifically with hunger in America. The commission concluded that the Food Stamp Program had been effective in solving most hunger problems in the United States. It argued against restrictive budgetary ceilings on the Food Stamp Program and urged greater efforts in making sure that groups such as American Indians and the elderly were enrolled as participants. Space limitations preclude full development of the "hunger in America" portion of the *Report* in this essay.

[5] This view of the 1980s is developed much more fully in Falcon, Pearson, Timmer.

[6] The *Report* strongly urges an international agreement on grains that includes substantially increased reserves. However, the technical problems with international agreements and their recent history do not inspire confidence about the likelihood of their being successful in the 1980s. Moreover, any new grain agreement must be able to reconcile both North/South and East/

This is not an essay to develop fully a prognosis for the 1980s. However, the foregoing comments, cryptic as they are, have important implications for an assessment of the *Report* and for suggestions on future public policy on world hunger.

First, by not laying out more carefully a broader view of the world food economy of the 1980s, the commission failed to stress the increased likelihood of difficulties in solving hunger problems. Such a view of the world also would have given much more force to the commission's recommendations on trade, debt restructuring, compensatory finance, and food security.

Second, a more interdependent view of the 1980s (with respect to countries, commodities, and hunger/commercial issues) would have added support to the commission's theme on self-reliant production within low income countries.

Third, a broader view of the 1980s also might have permitted the commission to take a stronger stance on some areas in which the United States should be cautious—for example, highly subsidized corn-based ethanol plants.

Program Elements for the Future

Most of the commission's *Report* is as relevant for President Reagan as it was for President Carter. Global hunger continues to persist, and if anything, it is more likely to be a destablizing international influence in the future than it was in the past. At the risk of making very difficult issues sound superficial or the solutions seem easy, the case for a renewed American focus on hunger alleviation can be broken down into seven operational propositions. On the whole, these principles are consistent with the *Report*, although they also reflect personal preferences and the political changes that have occurred since the termination of the commission.

(a) Given an increasingly interdependent food world, the hunger topic is an appropriate focus for America's relationship with developing countries. Of all the broad areas in which the United States could play an important leadership role, food and agriculture would seem to be preeminent. The extraordinary productivity of American agriculture, the well-(indeed over-) fed character of the American people, and the dominance of the United States in the global food system give this country credibility in the food area as perhaps in none other. Moreover, a concern with the poor and malnourished, especially children, is very much in the American tradition.

These widely recognized points, however, may be necessary but not sufficient conditions for making hunger a central focus of development assistance. If hunger is poverty-related, as seems clearly the case, it is not a tidy area in which to involve an assistance program, nor is it the only important problem facing developing countries. Moreover, the vastness of the hunger problem may be out of balance with the size of America's aid commitment. Finally, it is abundantly clear that hunger issues go to the heart of the political economy of many nations. In some countries American concerns about hunger will go unheeded or be counterproductive, and in virtually all countries, most of the resources and difficult decisions will be of a domestic nature. Nevertheless, the hunger area seems to be one in which greater amounts of both public and private support can be mobilized within the United States.[7] More generally, food is a topic which, if not handled properly and expeditiously, could have far-reaching international consequences during the 1980s.

(b) A focus on hunger means a primary emphasis on agriculture and rural development. If hunger alleviation is made a focal point of American development assistance, such a concentration implies a concomitant emphasis on agriculture—but not for the reason that most people believe. Increasing food output is obviously important, especially in those societies with rapidly increasing populations and incomes. In terms of reducing hunger, however, the employment and income effects of agriculture are much more important than expanded food output per se. Although urban poverty and hunger may be more acutely visible, the overwhelming numbers of undernourished people are in the countryside. Many (perhaps 60%) of these individuals do not have direct access to land. These decentralized and

West negotiating stances. Under these circumstances, the United States probably can be of greatest assistance by helping less developed nations with the production, financial, and storage flexibility these countries need to accommodate international price instability.

[7] The Gallup Organization was employed by the commission to undertake a poll of Americans about world hunger. The results indicated a widespread misunderstanding of the severity and nature of PCM problems. They also showed that, in relative terms, Americans were very concerned about world hunger issues.

often forgotten groups are also among the hardest to reach with direct consumption programs within the public sector. In the absence of thoroughgoing agarian reforms, the key to reducing hunger problems is through additional productive jobs. The distinction between food production and income generation is an extremely important point—one often missed by agriculturalists and proponents of *Food First* (Moore and Collins). It also underscores the urgent need for choice of technique analyses based on social profitability rather than on preconceived notions of what should be considered "modern."

(c) A primary emphasis on agriculture means increased focus on relevant agricultural technology. In the commission's deliberations, the issue of agricultural technology was hotly debated. Part of the controversy had to do with the problems of tractors and mechanization in "labor-surplus" areas and part with the failures of introducing annual crops on delicate forest soils. Issues surrounding seed technology and the appropriate use of fertilizers and pesticides also fueled the debate. At least in part because of these controversies, the *Report* was largely silent on the importance or limits of agricultural technology in an assistance strategy for the United States. This silence may have been one of the most severe limitations of the commission's analysis.

In spite of much-heralded developments in wheat and rice, involving now some 50 million acres mainly in the irrigated regions of Asia, the overall record on improved seed technology is rather poor. New developments with open-pollinated corn varieties reengineered for tropical conditions will soon be available, and new packages for sorghum and millet also offer substantial prospects. There is active research underway as well for beans, cassava, and vegetables that promises to be relevant. Nevertheless, in assessing technology needs and accomplishments to date, it is clear that much research is needed, especially for rainfed agriculture. Fortunately, the general area of agricultural research is one in which the United States has a comparative advantage. Many of America's processes for developing technology are certainly relevant even if much of existing American technology is not directly transferable. Technology is also an area where both the public and private sectors in the United States have much to contribute, as do the universities—even some that do not belong to the land grant fraternity!

With a limited development assistance program, finding an appropriate niche for American involvement is extremely important. For example, land reform may be more vital than technology in alleviating hunger in some regions, but American efforts to promote agrarian reform in other countries are almost sure to be counterproductive. By avoiding some of the mistakes on technology that have occurred in the past and by recognizing that technology cannot solve all the problems of development, it should be possible to develop a large, positive program in this field. Fortunately, many of the relevant institutions (for example, the Consultative Group on International Agricultural Research (CGIAR) and the Board of International Food and Agricultural Development (BIFAD), are in a position to make this technological promise a future reality.

(d) For agricultural technology to be effective, large investments will be required, especially in such fields as water resource development. Presumably neither the Carter nor Reagan administrations have been particularly happy with the price tag that the commission attached to hunger alleviation. Unfortunately there are no "cheap fixes" on food and agriculture, and the commission called for a rapid tripling in the appropriations for foreign aid, much of which was to go for hunger causes. Particularly at a time when cuts in expenditure are the order of the day, such a recommendation requires further comment.

Although there always has been a limited lobby on foreign aid, it seldom draws the passionate support of many other allocations. In recent years, this problem has been accentuated by an unusual combination of political forces. Many on the political right have seen foreign aid as a costly giveaway to be stopped. The left has become so enamored with the "small-is-beautiful" syndrome that they have significantly downplayed the very real investment costs that will be essential if third world nations, with external assistance, are really to attack hunger. The net result has been an increased number of restrictions on aid allocations, such as on rural infrastructure, and a deceleration in the level of aid authorizations.

These effects can be seen in the official review of overseas development assistance published by the OECD. In 1979, for example, the United States ranked fifteenth among DAC countries in terms of its percentage of gross national product (GNP) devoted to bilateral and multilateral assistance to developing

countries. Indeed, with only 0.2% of GNP devoted to aid, the United States share exceeded only that of Italy and Austria among the seventeen nations that make up the Development Assistance Committee. The specific rationale for a larger American share will be discussed later, but a *prima facie* case for larger sums can be made just on the basis of the foregoing data.

Two cost components deserve special comment in the context of hunger. One of the severest problems in improving the nutrition of hungry people involves water resource development. The Asian concentration of hunger has already been mentioned. Moreover, by the year 2000, about half of the entire world's population will live in areas defined by the ten largest river basins in Asia. These basins, with their problems of irrigation, erosion, flooding, salinity, and drainage, contain many of the world's poorest people. Without some improved control over the production environment, the potential for new agricultural technology is limited. If unprecedented migration and other problems are to avoided, substantial investments will be needed to create dynamic rural communities where productive employment and incomes can increase. Most of the resource mobilization will have to be accomplished locally, but international resource transfer also is vital. Because many of the basin problems cross borders and involve several countries, outside agencies have a particularly crucial role to play. Regrettably, there is no cheap way out on this investment issue. People who want to attack hunger without significantly adding to the investment totals are kidding themselves or each other.

Second, for both the technology and water resource fields, there are important roles for both bilateral and multilateral initiatives. The *Report* underscores the complementarity of both approaches and urges strongly American support of the soft-loan window at the World Bank (IDA) and the international agricultural research effort the World Bank coordinates. Similarly, the commission's suggestions on debt restructuring are in the same general direction, since debt rollover in many instances is identical with increased flows of untied aid. While the investment needs are large, they are not beyond the capacity of the world to manage. The International Policy Research Institute (IFPRI), for example, suggests that an additional $7 billion investment annually (in 1975 dollars) during the decade of the 1980s would increase the annual world cereal output by nearly 200 million tons by 1990 (Oram et al.). This sum compares with the approximately $80 billion supplied to less developed countries in 1979 from external aid and loan resources.

(e) *For technology and institutions to pay off, a substantial reorientation in economic policy will be needed in less developed countries.* One seemingly curious feature of the *Report* is its simultaneous emphasis on trade and self-reliant growth. When put in a slightly broader context, however, this contradiction disappears.

The recent growth in world cereal trade has been very large; it has also begun to substitute for domestic stockholding. Whereas global cereal trade in 1980 was approximately three times larger than in 1960, ending world grain stocks in 1980 were absolutely smaller than in 1960 and only about half as large relative to annual production. For reasons alluded to earlier, some slowdown in the growth of trade can be expected, probably accompanied with rising and more variable international prices of grain. While cereal trade clearly will continue to be important for many "hungry" nations, the costs of an international "solution" to their food problem likely will be higher in the 1980s. This view of world trade thus provides a logic for an increased emphasis on domestic growth in agriculture to supply both food and employment.

Technology and investment provide two legs of the productivity triangle, while price and trade policy supplies the third. In general, low income countries tend to discriminate against the agricultural sector and to provide less than international prices to their farmers. For a long-run production solution, raising prices to farmers in many countries is absolutely essential. However, it is more than sheer neglect or urban bias that keeps governments from making this change. Higher food prices also mean lower real incomes, especially for poorer groups who may spend up to 80% of their incomes on food. This basic pricing dilemma—short-run consumption losses versus long-run production gains—needs to be recognized for the very real problem that it poses, even for the most responsible government. Too many analysts have been content to deal only with the production issue. Neither AID nor the World Bank, for exam-

ple, has been willing to do much in quantitative terms in support of consumption/nutrition projects or in aiding transition programs designed to put in place new food price policies. A sympathy toward this basic consumption-production dilemma and a willingness to use food aid and other types of development assistance toward new policies are critically needed-if the United States and other donors are to be helpful in solutions to the food problems actually faced by low income countries.

Unfortunately, the *Report* is largely silent both on the price-policy dilemma and the further complications this problem creates with respect to consumption programs. Untargeted programs, such as physical rations for everyone, have high relative resource costs in poor societies. On the other hand, the administrative problems involved in reaching only the poorest groups, especially in rural areas, are immense. Helping to resolve this dilemma will be a task on which agricultural economists can make an important contribution in the years ahead.

(f) It is in the economic and security interests of the United States to assist in hunger alleviation and in the creation of a more stable world food economy. The redirection and expansion of American assistance to help fight global hunger that is being suggested here raises the obvious question of whether such changes would be worth the price to the United States. The commission took the view that recommended programs would have little chance politically unless the suggestions could be shown to be rather directly in America's own interest.

Such a view will perhaps be abhorrent to humanists, but they will be pleased to know that the commission answered the self-interest question with an unequivocal "yes." The basis for this affirmative assessment was twofold. The first element stressed growing economies and trade, using rather traditional arguments. The second explanation, and by far the more important, stressed the national security implications of food. The fact that several of the nations with substantial hunger also have a nuclear capability was one aspect of the argument, but not the major element. More broadly, food in the 1980s was seen as a potentially destabilizing force—in the manner, if not the same magnitude, that oil had been in the 1970s. Lest that view be casually discarded, one need think only of recent food crises in Poland, Russia, Egypt, Kampuchea, and Ethiopia. Consumption (though not necessarily hunger) issues were central in each case, and in several of these examples, the potential for international conflict was clearcut. This broader view of security would seem to be a natural complement to the military expenditures that have taken on a heightened priority under the new administration.

(g) Given that hunger alleviation is in the self-interest of the United States, substantial changes will be required in American attitudes and capabilities for working with developed countries. If the United States chooses to make hunger issues the center of its development assistance effort, more than marginal changes will be required. Additional dollars will be needed in support of research and investment. The Agency for International Development will have to overcome its inadequacies in technical competence to deal with food and agricultural issues. The United States will need to seek new kinds of formal relationships with several key nations. Above all, the president and Congress will have to lead. Most of the leadership involves doing new things, but it sometimes involves not doing things as well—not attempting to use food as a political weapon, not promoting uneconomic gasahol installations, and not failing to recognize the severity of the hunger problems, even in countries whose governments the United States dislikes.

With a clearer sense of direction, the United States is now in a unique position to assist countries in helping to solve one of the worst problems of mankind. Without renewed efforts on the part of the United States and all countries, however, global hunger problems will become more acute and destabilizing before the end of the century.

Reflections on the Presidential Commission on World Hunger: Discussion

Marcelo Selowsky

I have three sets of remarks. First, some general reactions to the President's Commission report, particularly the section on implications for the United States' effort to combat world hunger; second, some specific comments on Falcon's paper; third, some further thoughts.

My Reactions to the *Report*

First of all, the commission must be congratulated for forcefully stating a very important fact still not fully recognized: that hunger and low levels of consumption in poor countries and poor families will not be solved by increasing the aggregate world or country's supply of food. Chronic hunger results from a lack of purchasing power by poor countries and poor families when they compete for that aggregate world or country supply. The problem is not a lack of supply but a lack of effective demand by low income population groups. This is corroborated by the fact that many countries have become exporters of grains while important segments of their population still suffer from malnutrition.

The report singles out several actions to increase the long-run earnings opportunities of poor individuals so as to solve long-run poverty and thereby long-run hunger. This is welcomed. But in many countries, poverty elimination is an objective in its own right. For other countries a poverty elimination strategy, as a means to solving the hunger problem, may have political constraints or trade-offs with other objectives, such as long-run growth. However, in these latter countries, governments might be interested in solving hunger as a separate objective from general poverty elimination. Hence, they might be interested in more quick, direct, and cost-effective instruments to eliminate hunger. In my view, given that the objective of the commission was to address hunger and not poverty, a stronger emphasis on these direct instruments should have been given. This includes an emphasis on a better use of the existing foreign aid and domestic resources that countries are currently devoting to food supplementation programs, food subsidies, etc. I will come to this later.

The commission repeatedly refers to the necessity of a more self-reliant food system in developing countries. It is not exactly clear to me what is meant. I hope it is not a call for a higher degree of self-sufficiency in food. That would be tragic. Fluctuations in food consumption in poor families results from fluctuations in their regional supply of food or fluctuations in their earnings. Internal and international trade in food helps to even out these fluctuations in consumption and not the reverse.

Comments on Falcon's Paper

Wally Falcon's paper represents an interesting afterthought by a member of the commission, particularly in his further elaboration of the economics of the hunger problem. The paper presents several operational propositions to eliminate hunger. I do not have a particular quarrel with them; however, it is not clear whether these propositions represent facts or simply working hypotheses requiring empirical validation. A more explicit presentation of the economic criteria under which to accept or reject these hypotheses would have been useful. Let me give some examples by quoting some of these operational propositions.

"A focus on hunger means a primary emphasis on agricultural and rural development." The paper is careful to state that the relevant effect on hunger is via the income or earnings effect and not via the supply of food, i.e., it clearly recognizes purchasing power as

The author is economic adviser of the Development Economics Department of the World Bank.

These comments reflect the views of the author and do not necessarily reflect those of the World Bank.

the constraint. However, the income effects of agricultural and rural development are basically relevant to small farmers. How relevant are they for the landless and urban poor? Even if the hungry are concentrated among small farmers, the cost of raising rural incomes could be substantial if the rates of return on those agricultural investments are low. In that case subsidization of those investments will be required. The success of effectively reducing hunger through this strategy depends crucially on the rate of return to investments in small farmers. What is the empirical evidence on it?

"The key to reducing hunger problems [among the landless] is through additional productive jobs." This requires further elaboration; what are "productive" jobs? Why do we have today less than an "optimal" volume of "productive" jobs? Is this the result of market failures (i.e., gaps between shadow and market wages) or government interventions (i.e., taxes on agricultural exports)? Some elements of welfare economics are required in discussing such a proposition.

"A primary emphasis on agriculture means increased focus on relevant agricultural technology." But, what is "relevant"? What is the room for maneuvering for foreign aid in this field if technological choices are heavily influenced by wrong domestic (factor) price policies?

"For agricultural technology to be effective, large investments will be required, especially in such fields as water resource development." But, what is the evidence on the rate of return to investments in water development? If it is high, why have countries not done it? Is it because there are strong discrepancies between private (or government-perceived) returns and social ones, i.e., short government horizons?

In my view a useful way to organize these policy choices is to set up first an acceptable criteria in welfare economics: how to increase food consumption in poor families, (*a*) given fiscal constraints on aggregate subsidies and, (*b*) minimizing any trade-off with efficiency and growth. The general option emerging is a policy that maintains world prices to food producers but brings down consumer prices for malnourished families. Why would subsidies on investment in water or rural job promotion be better? Specific discrepancies between social and private signals in those sectors must be identified before making judgments on their desirability.

Some Further Thoughts

I believe that the highest payoff in an effort to reduce chronic hunger comes from increasing the effectiveness of existing food aid and domestic food programs and food price subsidies. This is particularly true in countries already spending considerable resources on such programs. There are two areas to examine.

The first is to evaluate whether many of the existing international food aid programs, as well as domestic programs, have effects on food consumption no larger than an equivalent foreign exchange or income transfer. If governments are already importing grains, part of the concessionary food aid will replace old imports. The net addition to the internal supply of food will be equal to foreign exchange transfer times the public sector's marginal propensity to import food. The same is true for some typical domestic programs distributing inframarginal amounts of food, e.g., ration shops. If these marginal propensities (on the part of governments or poor households) are low, it is worth looking for changes in the ways these programs are being implemented (for a given amount of aid or domestic food subsidy). Food aid could be made contingent on the country keeping its old level of food imports constant. Similarly, food stamp programs charging a price equal to previous levels of consumption but offering a stamp value in excess of that level would be substantially more effective per dollar of subsidy.

In several countries substantial subsidies are being concentrated on a few food commodities therefore inducing important substitution effects. The net effect on calorie intake is not at all obvious and depends on the gross cross-elasticities among these foods. We still do not know the magnitudes of several of these key elasticities. The problem becomes more difficult when programs introduce new foods, i.e., baby foods, fortified cereals, etc. Here substitution effects cannot be measured with past data, and experimental data becomes of relevance.

Reflections on the Presidential Commission on World Hunger: Discussion

T. N. Srinivasan

I will organize my remarks around the following broad questions: First, has the Commission diagnosed the malady of hunger correctly and reasonably accurately estimated its dimensions? Second, has it arrived at appropriate policy recommendations, based on currently available knowledge? Third, are the recommendations balanced in terms of relative emphasis on policies to be pursued by individual countries versus international policies, on production versus distribution, on self-sufficiency versus dependence on international markets, and indeed, on reliance on markets in general versus government interventions?[1]

The Commission was misled in its diagnosis by its adoption of the analytical framework of Reutlinger-Selowsky. This and the earlier studies in India by Ojha, and Dandekar and Rath are based on improper use of the protein and calorie requirements put together by the United Nations Food and Agriculture Organization (FAO) for assessing undernutrition. Of course FAO had clearly warned that comparisons of recommended intakes with food consumption "cannot in themselves justify statements that undernutrition or overnutrition is present in a community or group as such conclusions must always be supported by clinical or biochemical evidence" (FAO 1973). I have discussed some of these issues in a paper published last March (Srinivasan). The essential point is that an individual, while remaining in good health, maintaining body weight, and performing activities that require the same energy expenditure, is nevertheless found to vary his energy intake over a wide range. In addition, individuals adapt to sustained heavy or low intakes by adjustment in body weight and/or physical activity. Further, as Sukhatme has shown, the daily energy balance, i.e., the difference between energy intake and energy expenditure, appears to follow an autoregressive stochastic process. Because of this autocorrelation, even the average of intakes over a week, or even a month, does not adequately dampen the variation in intake. In such a situation, comparing average intakes with the average "requirements" to determine the nutritional status of a group of individuals is dubious even if the group is homogenous in age, sex, body weight, and energy expenditure on physical activities. Indeed, available studies, such as those of Ferro-Luzzi et al., show that clinical evidence of undernutrition and nutritional inadequacy, as judged by shortfall in intakes compared to requirements, does not match. Controlled experiments by Edmundson, with similar individuals given diets of differing calorie content, demonstrated that energy expenditure adjusts to intakes without changes in body weight or physical activity through changes in efficiency of conversion of energy intakes into usable energy.

The comparison of average intakes with "requirements" often overstates the extent of real malnutrition; Bhalla, using U.S. data, shows that such a procedure classified more than 50% of the U.S. population as undernourished. If rough allowances are made for intra- and inter-individual variations in intakes, the estimated extent of undernutrition in a population often comes down substantially. Sukhatme's estimate of undernutrition in India is of the order of 15%–20% of the population and not the 50% or more as unadjusted estimates would suggest. Whether or not a reduction of this order should be called fine-tuning, as Falcon suggested, exaggerating the numbers of undernourished would only make the already difficult problem appear insolvable. In addition, it attributes the prevalent malnutrition to inadequate calorie intakes,

---

T. N. Srinivasan is a professor of economics at Yale University's Economic Growth Center.

[1] I confess I read only the thirty-page summary of the Commission's report. Reading Falcon's paper assured me that the summary is fair and has not omitted any essential features. However, if any of my critical remarks are adequately answered in the full report but not in its summary, I apologize to Falcon and through him to the other Commissioners.

whereas in fact morbidity caused by gastrointestinal and other ailments arising out of unsafe drinking water and poor sanitation is perhaps equally or more important as proximate cause.

The Commission's diagnosis that over the longer term hunger can be eliminated only by eliminating its causes—poverty and insecure food supplies—is not wide of the mark, though it is hardly original. However, the Commission does not appear to have looked into the experience of some developing countries where, in spite of poverty, very creditable achievements in the area of nutrition and health have been recorded; and of others at the other end of the spectrum where, in spite of relatively high per capita income of the country, significant sections of the population are deprived. Sri Lanka and Kerala State in India fall into the former category and Northeast Brazil into the latter.

The Commission emphasizes that the elimination of hunger is in U.S. national security and economic interest. As such, the United States should make it the major focus of its relationship with the developing world. Falcon apparently agrees. But the national security angle, like the earlier use of the Communist threat as an argument for economic aid, is unlikely to impress many congressmen or senators, let alone the U.S. public at large. The fact of the matter is that, as Dr. Falcon himself notes, the poor and hungry are rarely the wielders of political power in any country. The power elite, in spite of their rhetoric, do not often perceive it to be in its self interest to divert resources to the poor and hungry.

The recommendations that the United States should work toward multilateral reductions in tariffs and nontariff barriers to LDC exports is, of course, unexceptionable. But whatever it may do to augment the exports of LDCs and improve efficiency of world resource allocation, its impact on the poor and hungry is not that direct. The same is likely to be true of commodity agreements that attempt to stabilize or increase export revenues of LDCs, assuming for a moment (contrary to experience) that they do succeed in doing so. It is not often the case that export crops are produced by small farmers. Debt write-off and raising the grant element in U.S. aid are also laudable, but again the link with the elimination of hunger is at best tenuous. However, all these recommendations and the exhortation that the United States raise its development assistance to 0.7% of its GNP are non-starters in today's climate, if ever they were.

The Commission recommends that the United States should give assistance primarily to countries meeting the basic needs and rights of the people. I am afraid that any direct linking of bilateral aid to specific domestic policies will be viewed by recipient countries as unwarranted interference in their domestic affairs. In an increasingly complex economy, it is possible that investment in infrastructure may be more productive and will help reduce poverty more than direct investment in food production, at least in some countries. Thus, excessive emphasis on meeting basic needs and rights in the short to medium run may go against meeting them in a sustainable way in the long run.

The Commission also recommends that the United States should put more emphasis on nutritional goals. Apart from the difficulty of defining the problem, assessing its extent, identifying its causes, and prescribing solutions, there are several other operational difficulties, some of which are identified by Falcon. It is not as if there have been no attempts to identify subpopulations at risk, such as children, pregnant and lactating mothers, and to target programs toward these groups. The applied nutrition program and the scheme for the midday meal for school children in India indeed were such programs. These were initiated long ago and are still being implemented. Studies evaluating these programs are also available. Had the Commission looked at this experience, they would not be so optimistic about achieving nutritional goals. Simply put, a major problem, mentioned by Falcon, is that because the household is the decision unit, any provision through the government of food designated for one member of the household—be that person a school-going child or a pregnant mother—will result in that member being supplied less from the household pool. Thus, even though the government supplies food to the target members of the household, the food more or less acts as an income supplement to the household as a whole. The target group members will not receive full benefit.

The Commission recommends that more research be done in the United States on improving agriculture in the developing countries. I would rather have recommended technical as-

sistance to LDC research institutions. In this way the research capability in the LDCs will be strengthened.

The Commission appears to me to be "dirigé" in its approach, in that it has inadequately emphasized the role of markets. The approving reference to self-sufficiency as a goal for each LDC leaves the impression that the Commission does not think much of comparative advantage. The minutes of dissent indicate that some Commissioners wish to go even further and embrace the proposals of some radical LDC economists by suggesting that the LDCs "delink" from the developed world. They recommend that U.S. aid and food aid be stopped altogether in the hope that it would force LDC governments to pursue what they call "basic needs"-oriented policies. Apart from the lack of content or coherence of a "basic needs" strategy of development—if one can indeed define such a strategy—the naivete or, worse still, cold cynicism behind such a proposal is appalling. They ought to know that any delinking and cutback in aid is certain to hurt the poor and hungry more than any other group.

The Commission has not emphasized enough the basic fact that what really matters from the point of view of elimination of hunger are the domestic policies and institutions that govern resource allocations in agriculture, as well as income distribution within agriculture and in the economy in general. There is no easy or quick-fix solution to institutional reform. Nor is it simple to state the extent to which U.S. policies can aid or retard needed reforms. Good intentions and generalities are no substitutes for policies based on realistic assessment of the feasible, in specific, contexts.

Finally, the Commission could have explored further the implications of the emerging trends in international trade in food grains such as the following: (*a*) the increasing importance of middle income countries and oil exporters in the market for food grains, (*b*) the fact that these countries and the Soviet Union wish to import grain for expanding their livestock and increasing meat supplies, (*c*) the already concentrated grains market is becoming further concentrated in terms of few supplier countries and companies facing importers, some of whom are state trading organizations, (*d*) the disappearance of U.S. food stockpiles that stabilized the trade in the sixties, and (*e*) the impact of the energy crisis on the prices and supply of chemical fertilizers on which any substantial growth in food output in LDCs depends. Each of these factors has serious, possibly adverse, implications for the elimination of poverty and hunger.

Economic and Environmental Consequences of U.S. Agricultural Trade Policy (George E. Rossmiller, Foreign Agricultural Service, USDA, Presiding)

Toward a U.S. Agricultural Export Policy for the 1980s

Alexander H. Sarris and Andrew Schmitz

In a recent issue of *Business Week*, a special article on the restructuring of the American economy paid particular attention to the agricultural sector and how it likely would be the prime fuel for inflation in the 1980s. The rationale behind this outlook was the projection that international demand for U.S. agricultural exports would continue to grow rapidly, while a combination of slower domestic agricultural productivity growth and sharply increased production costs would temper a contemporaneous increase in output. The article concluded by saying that "we certainly will need a federal policy on exports and in the next few years there is going to be an intense debate on that" (p. 74). The purpose of this article is to open such a debate on an appropriate U.S. agricultural export policy for the 1980s.

For the last decade, agricultural exports have comprised on the average roughly 20% of the total value of U.S. exports. Agricultural imports, on the other hand, have sharply and continuously declined in relative importance over the same period, from 15% of total U.S. imports in 1970 to 7% in 1980. The result has been a sharply growing agricultural trade surplus (from $1.5 billion in 1970, to $12.6 billion in 1975, to $23.9 billion in 1980) compared to a widening nonagricultural trade deficit (always in the red in the last decade and sharply increased in the last five years from −$20.7 billion in 1976 to −$47.2 billion in 1980).

U.S. agricultural exports are largely concentrated in grains (42.6% of the total agricultural export value in 1979–80), soybeans and products (24.1%), and cotton (6.7%), while a variety of animal products and tobacco comprise the major part of the remainder. U.S. agricultural imports, on the other hand, are less concentrated. Noncompetitive items with U.S. production, like coffee, cocoa, rubber, and bananas, make up 41.8% of imports in 1979–80. Among the supplementary imports, the largest shares are occupied by beef and veal (18.9% of total supplementary imports by value in 1979–80) and sugar (14.9%), the remainder being comprised of a wide variety of products.

Of particular importance to trade and the American balance-of-payment position is the growing share of U.S. agricultural production that is exported. Table 1 shows proportions of the major agricultural products and the share of total U.S. agricultural production exported from 1965–66 to 1978–79. Currently, about half of the total agricultural production is exported, while a decade ago the proportion was about one-third. The growing importance of trade for U.S. agriculture has implications that must be reckoned with in the 1980s.

Production Expansion to Meet Foreign Demand

In a recent series of policy papers (U.S. Department of Agriculture 1980a), the emphasis has been placed on increased U.S. agricultural production to meet the growing demand from abroad. Where is this growing demand bound to come from? Table 2 presents the United Nations, Food and Agriculture Organization (FAO) projections of increases in world export availabilities and import requirements for the major U.S.-traded products for 1985. An important conclusion that these data support is that the major new markets for expanded U.S. agricultural exports (and, in particular, grains, oil seeds, and cotton) will be the developing countries, while the importance of many traditional markets, such as Western Europe, other developed economies, and the USSR will decline in relative terms.

The authors are, respectively, assistant professor and professor, Department of Agricultural and Resource Economics, University of California-Berkeley.

What are the costs of expanding U.S. agricultural exports? Is a policy aimed at increased production only one more means by which importers operate in a trading environment where buyers rather than sellers dictate the terms of trade? The key issue here is the nature of comparative advantage for the United States when price supports, research and development expenditures, subsidies, etc., are taken into account (Edwards and Freebairn).

The United States and other grain exporters, such as Canada and Australia, are promoting all-out production to meet demand from abroad. Consider a policy which increases production through increased expenditures on research and development. In figure 1 domestic demand is D_d, and foreign demand is D_f. With a supply surve, S', exports are OQ_1. Now what are the effects of investing in research and development which yields a technological change such that S_t results? Quantity of exports expands to OQ_2, and total export value becomes OP_2bQ_2 which is larger than OP_1aQ_1 if the export demand curve is reasonably elastic. Who are the gainers from the push toward production expansion? While the consumers in the exporting country gain $P_1a'b'P_2$, the foreign consumers gain P_1abP_2, which is even larger, since export demand is such a large share of total demand. The producers' gain, $p_2gh - P_1ef$, is positive if the supply shift is parallel. However, if the shift makes the supply curve more elastic, the producers could certainly lose, and the loss could even exceed what the domestic consumers gain.

Also, note that exports have increased in

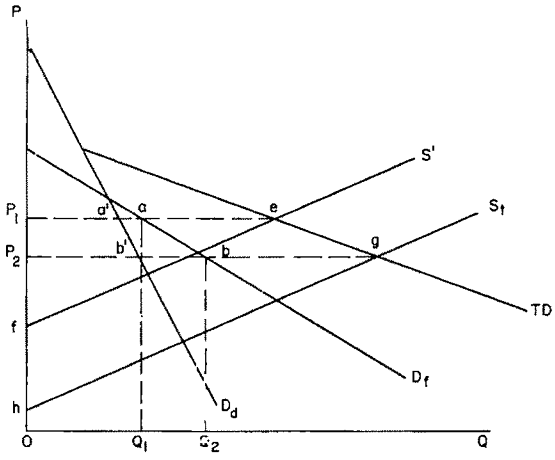

Figure 1. Increased production via research and development in international trade

both quantity and value terms, but there has not been a shift in foreign demand in the sense that the schedule, D_f, has shifted to the right. The true statement is that exports have increased both in terms of quantity and total value because of policies in exporting countries which have lowered the real price of food exports. In terms of data, if P_1Q_1 and P_2Q_2 were observed over time, one cannot necessarily conclude that there has been a growth in exports in that they have grown at some constant real prices; exports could have increased because of lower real prices. It is clear from figure 1 that policies can be introduced which result in an increase in exports, but the benefits from such policies can go largely to importers. A country should not necessarily be proud of the fact that its exports are expanding!

There may be an important reason why exporters are pushing for increased production. Given the current political climate, Australia, Canada, and the United States are competing for export markets (McCalla, Schmitz, Storey). As a result, Canada, for example, to maintain its export market share, also has to push for increased production, which it has recently done by trying to increase production by 30% above past levels.

From the above analysis and data, the conventional wisdom, as expressed in the quoted *Business Week* article, that there are vast and growing international markets for U.S. agricultural products should be interpreted with caution. This growth might not occur if the marginal cost of production expansion in the United States had to be covered by the marginal return from the export market. Second, the uncertain question that emerges is whether the developing countries, as a whole, can afford to purchase in the international market the immense quantities of food and feed crops that they will no doubt require, given that many of these nations face acute foreign exchange shortages because of the energy crisis and already heavy external indebtedness. A further unknown factor is whether the various efforts toward food self-sufficiency via intensification and technological adaptation methods in agricultural production in those countries will significantly modify downward the already-mentioned FAO import requirements (cf. table 2).

Another factor that should temper the unfettered optimism of those that envision everexpanding U.S. agricultural export markets is the rising agricultural protectionism in the major developed importing countries in the recent years. In the EEC, for instance, Sampson and Snape and Jabara showed that in the last few years the ad valorem tariff equivalent of the variable levies is approaching the levels of the early 1970s after a period of low protective levels. This rising relative protectionism is not the result of increased political power of farmers in many countries. It is rather the result of generally softer world markets (partly because of larger U.S. export supplies) coupled with fixed nominal agricultural internal price levels. It is probably not farfetched to assume that in the early 1980s the world agricultural scene presents a similar degree of "Disarray," as Johnson computed for the early 1970s.

Is Instability Going to be the Villain?

The trends analyzed above, namely, the increased share of U.S. agricultural production that is exported and the projected relative shift of U.S. agricultural export markets toward the developing countries combined with the openness of the U.S. market, suggest that the real serious problem in the 1980s could well be a growing instability in the agricultural sector. Large price fluctuations in the agricultural sector can lead just as easily to inflation as can continued shortages. The 1972–75 commodity price boom provided an example of how inflation can follow from commodity instability (Cooper and Lawrence).

To analyze how the changing structure of

the market for U.S. exports (as suggested by table 2) impinges on domestic price stability, consider a simple model for one commodity. Let domestic supply, domestic demand, and demand for exports be given by the equations:

$$S = S_0 p^{\alpha} u, \tag{1}$$

$$D = D_0 p^{-\beta} v, \text{ and} \tag{2}$$

$$E = E_0 p^{-\gamma} w. \tag{3}$$

In equations (1)–(3), S_0, D_0, and E_0 are the base period quantities of domestic supply, domestic demand, and exports, respectively; p is the domestic price (equal to the international one) which is equal to one in the base period; u, v, and w are multiplicative random disturbances with means equal to unity, uncorrelated over time, and independent (for simplicity); and α, β, and γ are all positive constants equal to the short-run price elasticities of domestic supply, domestic demand, and export demand, respectively. The short-run market equilibrium condition that determines the equilibrium price is

$$S = D + E. \tag{4}$$

Denote by S_d, S_f the base-period shares of total supply that are absorbed by the domestic market and exported, respectively ($S_d + S_f = 1$), and by x^*, the proportional change of a variable from its basic value ($x^* \equiv dx/x_0$). The differentiation of equation (4) leads to the following expression for the short-run proportional price shift:

$$p^* = \frac{S_d v^* + S_f w^* - u^*}{\alpha + S_d\beta + S_f\gamma} = \frac{v^* - u^* + S_f(w^* - v^*)}{\alpha + \beta + S_f(\gamma - \beta)}. \tag{5}$$

Denoting by σ_v^2, σ_u^2, and σ_w^2, the variances of v, u, and w, respectively, the variance of the proportional short-run price fluctuations (to be denoted by σ_p^2) can be written as

$$\sigma_p^2 = \frac{\sigma_v^2 + \sigma_u^2 + S_f^2(\sigma_w^2 + \sigma_u^2) - 2S_f\sigma_v^2}{[\alpha + \beta + S_f(\gamma - \beta)]^2}. \tag{6}$$

It is immediately evident from (6) that $d\sigma_p^2/d\gamma < 0$. In other words, if the price elasticity of demand for U.S. exports becomes smaller, then this will lead, *ceteris paribus,* to larger domestic price fluctuations. It has been observed as well as formally analyzed (Abbot, Sarris 1980) that the import demand of developing countries is highly price inelastic because of government interference in both domestic and external trade. If the destinations of U.S. agricultural exports become dominated by developing nations, as seems to be the trend, then the weighted price elasticity of demand for U.S. exports will diminish leading to increased domestic instability.

Assuming now that domestic demand fluctuations are miniscule compared with domestic supply and foreign excess demand disturbances, we can obtain from (6) a simple expression for the derivative of the domestic price variance with respect to the proportion, S_f, of domestic production that is marketed abroad:

$$\frac{d\sigma_p^2}{dS_f} = \frac{2\sigma_w^2(\alpha + \beta)}{[\alpha + \beta + S_f(\gamma - \beta)]^3}\left(S_f - \frac{\gamma - \beta}{\alpha + \beta}\,\frac{\sigma_u^2}{\sigma_w^2}\right). \tag{7}$$

Equation (7) suggests some interesting speculations. First, if $\gamma < \beta$, namely, if the price elasticity of foreign demand is lower than the price elasticity of domestic demand, then the expression in (7) is positive, suggesting that an increased foreign exposure of U.S. agriculture will imply increased domestic price instability. Given the extensive foreign government intervention in agricultural trade and the shift of U.S. exports toward more price inelastic developing countries, the hypothesis that γ is smaller than β does not seem farfetched. However, even if $\gamma > \beta$, then, as table 3 indicates, it is mostly for values of the ratio γ/β much larger than one that the possibility of a negative sign of $d\sigma_p^2/dS_f$ becomes real. Furthermore, it is much more plausible to hypothesize that foreign demand fluctuations are much larger than domestic ones. Looking down the columns where σ_u/σ_w is equal to .5, it can be seen that only when γ/β reaches 5—a rather farfetched possibility—does the sign of $d\sigma_p^2/dS_f$ become negative.

The above analysis suggests that, given export and market trends, a major problem for U.S. agriculture in the 1980s will be increased instability and not secular rises or declines in product prices.

Multilateral Reductions in Trade Barriers

Traditionally, the United States has advocated free trade in agricultural exports. At the same

time, however, supplementary U.S. agricultural imports, as well as principal exports, have been subjected to sizable trade barriers. For the former, Wipf computed that the total effective rate of production for sugar and syrup products in 1968 was 660%, while for dairy products it was 48%. Price supports for food grains and cotton in 1968 resulted in effective protective rates of 143% and 101%, respectively.

While the commodity boom of the mid-1970s reduced the effective protection rates to almost zero for most products, the recent years have seen a resurgence of U.S. protectionism. The yearly average differences between the United States and international sugar prices have been 14.7%, 34.3%, and 78.4% in 1976, 1977, and 1978, respectively. Wheat and feed grain payments to producers under CCC programs have reached $2 billion in 1978 compared to $360 million in 1975 and $330 million in 1976.

Table 4 gives some recent estimates of increased imports from free trade in selected products in the United States and the major U.S. foreign markets. Note that, for two of the most highly protected U.S. commodity categories—beef and dairy products—the aggregate losses to the United States from free trade (i.e., increased imports) are much less than what the United States would gain from export expansion due to trade liberalization abroad. This can be seen merely by looking at the projected increased imports of Japan alone and by considering the fact that the United States enjoys an 80% share in Japanese feed grain and soybean imports and a share close to 50% in some of the other products.

It may well be that importers of U.S. products are unwilling to lower trade barriers because the United States is unwilling to do so. Yet, as table 4 shows, it is certainly in the best interest of the United States to move to freer trade because the losers from more liberal trade could easily be compensated by the gainers, so all could be made better off.

In certain commodities the United States has, in fact, been unwilling to grant domestic producers protection through tariffs. For example, in the 1979 Mexican vegetable-dumping lawsuit filed by Florida producers, the United States ruled in favor of Mexico; hence, tariffs were not misused on Mexican exports of fresh winter vegetables to the United States (Schmitz, Firch, Hillman).

Importers of U.S. agricultural products, such as Japan, may have good reason to favor protection other than for the often-heard ar-

gument that protection is used to increase income of farmers. Studies have shown that tariffs do more than just protect farmers—they result in a welfare improvement for the country as a whole because the producer gains plus the tariff revenue more than offset the consumption losses. For example, Carter and Schmitz have shown that, for wheat alone, major importers have gained roughly $3.7 billion per annum from pursuing close to optimum tariff policies.

In addition to optimal tariff policies used by importers of U.S. goods, exporters to the United States may also be using their trade policies to their advantage. For example, Australian exports of beef to the United States are restricted by the use of voluntary quotas. Theoretically, one can show that the use of such quotas can give exporters monopoly power. If the exporter is able to collect the quota rent, it can, in essence, impose an optimal export tax by using a voluntary quota. Quotas can allow exporters to behave in a cartel-like manner against importers. The empirical results by Dodge suggest that this is what is happening with respect to exporters of beef to the United States. Thus, it may well be that importers of U.S. goods exert, consciously or not, monopsony power in buying; and exporters to the United States exert monopoly power in selling. This is certainly the worst of all possible worlds for the United States to be in. If this is true, it might offer another reason that countries who trade with the United States are resistant to alter substantially their trade policies.

Would the United States be willing to lower its agricultural trade barriers if its trade partners agreed to lower theirs? It would certainly be the best economic policy to pursue. Two recent developments seem to suggest that the United States could be more eager to do so in the 1980s. First, the income position of U.S. farmers, which always provided the rationale for restrictive policies, has improved considerably. While the average per capita disposable income from all sources of farmers stood at 71% of the average disposable income of the nonfarm population during 1965–70, the proportion in 1975–79 was 91%. Second, consumer interests are becoming much stronger politically and much more aware of the huge costs of past farm programs which only resulted in higher food prices.

Implications for Agricultural Trade Policy in the 1980s

It goes without saying that the United States has a dominant position in world agricultural trade. This position is bound to become more important, given the projections of table 2.

With this degree of market power, the relevant question becomes whether the United States can or should use this power to its advantage.

This issue and the desirability of production expansion in exporting countries, which was questioned earlier, are encountered in discussions of the implementation of a grain export cartel. In a forthcoming book (Schmitz et al.), it is demonstrated that production may have to be curtailed—at least in the short run—for optimal pricing to be achieved by exporters. In the long run this need not be the case. Given the tariff protection afforded high income importers, to be initially effective a cartel may have to reduce exports and production. Then, if importers respond, production may increase due to the movement toward free trade.

One of the key components of a cartel is cooperation among exporters. While the issue is important for wheat, it is much less important for feed grains because the United States is the major exporter. For a grain cartel to be effective, the United States, Canada, and Australia must have a cooperative production and export policy. As pointed out earlier, these countries currently seem to have a competitive strategy—a situation which importers enjoy immensely! The idea of a cartel is to gain rents from importers which the latter currently obtain from optimal tariff policies. As shown earlier, a policy among exporters of increased production to meet increased export demand does the opposite. Instead of raising price and total revenue (net of subsidies, etc.) as a cartel would, current policies lower price and reduce rent. Current policies only add to the buying power of importers.

In terms of export policy, a conflict arises between the domestic sector on aggregate versus producers. As Carter, Gallini, and Schmitz demonstrate, a government export cartel, which considers both producers and consumers jointly, is quite different from a producer export cartel established to maximize only producer returns. In the government cartel case, food prices are kept relatively low for domestic consumers. This is done by pricing grain for both food and feed uses below that charged to high income importers. This helps keep meat prices low as well. A producer cartel, in turn, will tax both domestic and foreign consumers.

While cartel-like policies might put pressure on high income importers to lower trade barriers, the United States must be considerate of developing country needs. Unless these countries can increase their agricultural exports (as Valdès and Zietz demonstrate, they could benefit considerably from OECD agricultural trade liberalization), a grain, and especially a food grain, cartel might contribute toward further balance-of-payment difficulties for them.

While production restriction policies could result in a situation where the United States could exploit fully its international market-size advantage, such policies could increase domestic price instability. As Sarris (1981) demonstrates, in such cases a buffer stock policy operated solely by the exporter with a stabilization objective could result in both higher expected welfare for the exporter and lower price variance than an optimal export tax policy. Given the likelihood of increased instability in the 1980s, a buffer stock policy operated by the United States could afford the best welfare *cum* stability outcome possible. A buffer stock, however, should not be the result of secular overproduction and used to support farm income as was the case in the late 1960s and early 1970s. It should have a clear stabilization objective which can be shown to help both producers and consumers. The farmer-held reserve provided a good example of such a stabilizing stock policy.

Cartel and buffer stock policies might not be as good as multilateral trade liberalization. However, unless the United States decides to lower its own agricultural trade barriers, not much should be expected from its partners. In such a situation, unilateral actions might be the only ones that serve producers as well as consumers in an equitable manner.

Interrelationship among Export Markets, Resource Conservation, and Agricultural Productivity

Earl O. Heady and Cameron Short

The growing export market for U.S. farm commodities, especially grain, over the last decade has become the basic source of modern farm prosperity. While the public invested in a multibillion dollar supply and marketing control program over several decades to provide agriculture an equitable share of national income, the effects were somewhat minute in improving farm prosperity and asset values compared to the quantum jump resulting from greater exports since the early 1970s. The sources of these increases, greater incomes and populations of developing countries, institutional changes causing the Soviet Union and China to enter Western markets, and generally higher per capita incomes and meat consumption the world over, has—barring the negative fallout of major wars—the prospects of furthering the demands for U.S. grain and food exports. This newly acquired prosperity and wealth for agriculture in the immediate future does not necessarily promise a continued payoff for the next generations of farmers. There are two potential reasons that maintenance and further growth may not benefit equally the next generations. One is the tendency of current generations to capitalize the future growth in demand and income for U.S. agriculture into present land values. They have already "banked" this future return to an extent that the current return on land investment is very low. While numerous agricultural economists have proclaimed that exports and export policies are the significant future issues of agriculture (Schuh), this is true mainly for farmers who are land owners and have been or will be able to take advantage of the tremendous inflation in land values, resulting from general inflation and the growth in export demand and domestic commodity prices, and realize huge gains in their asset values. Of course, their descendents who inherit these enhanced asset values similarly will gain. If land prices "inflate forever," owners of farm land and their offspring will continue to "gain forever," just as will holders of gold and scarce works of art if they "continue to inflate forever."

Without this "forever inflation," and with a long string of growing future incomes already capitalized into land values, future purchasers of these assets will not find "exports the magic secret to farm prosperity." Farmers then may realize a low return on resource values generated from current earnings, just as are current farmers, who also have a mammoth capital gain increment to augment operational income. Farmers of the 1920s, 1950s, and 1960s complained mainly because they realized a low rate of return on their resources. New purchasers of land are faced with exactly the same problem. The American Agricultural Movement, as its members capitalized enhanced exports future prices into land values and pressed for price supports which would maintain corresponding asset values and returns, conducted the most violent demonstrations ever staged by U.S. farmers. Prospects are that farmers of the year 2000 will still be claiming low resource incomes and the need for higher support prices. Growing exports and export policies give no promise of eliminating this seemingly ubiquitous problem of agriculture over time.

The second reason growing exports will not solve all economic problems for all future farm generations is the potential unreclaimable deterioration of natural resources used in farming. The mining of our groundwater supplies in the gigantic Ogallala Aquifer has somewhat

---

This is Journal Paper No. J-10282 of the Iowa Agricultural and Home Economics Experiment Station, Project No. 2105.

paralleled our growth in the exports through P.L. 480 and market forces over the last twenty-five years. Already the drawdown of the water table is causing some farmers to shift back to dryland farming methods. As groundwater withdrawals eventually drop to recharge levels and the irrigated area shrinks, we perhaps can claim that our former endowment of stock water resources was exported with the enhanced foreign sales of grain in the later decades of the twentieth century. The important point is: Export growth will not solve all adjustment and income problems of these farmers in the future.

Perhaps of more long-run importance to society is the level of exports which can be maintained and the set of technologies which can be used while productivity of U.S. agriculture is sustained in the long run. The major complex involved here is soil erosion and related environmental problems. Some agriculturists propose that we are exporting our top soil and future agricultural productivity along with the record amount of grain moving into international markets. Of course, many soil profiles are so deep that each ton of soil lost does not immediately lower productivity. Agronomists have estimated soil loss rates (t, or tolerance levels) which vary with soil type and climate and provide an approximation of the rate at which soil can be eroded before productivity declines become effective (Wishmeier and Smith).

There is considerable evidence that the interrelated forces of farm structure, enhanced exports, high commodity prices, and extremely inflating land values have encouraged a near-monoculture type of agriculture which is exploitative in nature and gives rise to high rates of soil erosion and related chemical runoff. Under present machine and crop technology systems, there is a strong pressure for farms to become large and highly specialized (hence, the increasing monocultural nature of farming). Becoming larger through land purchases is a popular way to increase wealth under inflating land values. Interest payments on borrowed funds lower income taxes and enhance current after-tax-income while generating long-term capital gains in land value appreciation. With mammoth capital outlays required for machinery and land purchases, plus the need for large and immediate cash flows to service interest and principal payments, many farmers are, as one of our farmer friends puts it, "forced to farm the land like hell." While present or potential productivity may be declining, the farmer can accumulate more land and gain automatically as long as land value inflation continues. A part of rapid land value inflation has been indirectly due to export volume in recent years. To an extent, investment in farm land becomes akin to investment in aged tenement buildings in larger cities; repair of depreciation can be foregone with financial advantage if real estate values maintain a satisfactory inflation pace.

There is considerable belief and some evidence that high exports and the associated high commodity prices and land inflation have accentuated soil erosion on many fragile soils of the nation. So great has this concern become that a number of public bodies and institutions have begun to delve into it. Included are the activities of the National Academy of Science (National Research Foundation), the Office of Technology Assessment, Resources for the Future, the Conservation Foundation, the North Central Regional Research Committee-III, the U.S. Department of Agriculture through its monitoring and analysis work of the Resources Conservation Act (RCA) and a consortium of Land Grant Universities, the U.S. Department of Agriculture, and most of the professional societies representing agriculture (Hauser). More empirical evidence needs to be gathered. However, there is growing quantitative evidence that soil loss rates have accelerated in the last decade, with the realized or potential twin effects of reducing land productivity and furthering nonpoint pollution of our streams.

While some progress has been made in conservation tillage methods and conventional conservation practices, there also has been an accentuated shift to crop specialization such as the corn-soybean patterns of the Corn Belt on both level and hilly land. These semimonocultures, another representation of farming structure as it moves to larger and more specialized farms, give rise to higher levels of soil erosion than did the meadows rotations and diversified farming systems of previous decades.

A larger acreage of row crop, the shift to a near-monoculture and the advent of huge tractor and machine units which cannot readily be used with terraces and contouring interact with the high commodity prices and land values which have been associated with growing exports over the last decade. Studies at different times in Western Iowa show a large

increase in soil loss (Blase and Timmons, Hauser, Larson). Timmons reports an increase of nearly 25% in erosion rates in Ida-Monona-Hamburg soils in Iowa in less than twenty years and projects large increases over the Corn Belt (Schuh, Timmons 1979a). Of course, the incorporation of set-aside land from the early 1970s, as exports exhausted surplus stocks and negated the need for grain supply controls, also has contributed to greater erosion. Typically, this was somewhat marginal land.

Tradeoffs between Export and Soil Loss Levels

Certainly at some high levels of sustained exports, in conjunction with certain technologies that might be used in agriculture, soil erosion and agricultural productivity must become important national problems. Extremely high export levels may be attained in the short run which cannot be maintained in the long run if agricultural productivity is to be maintained. A trade-off curve between export levels (in total production levels for domestic or export use) does exist according to a set of models which we have had operational over a number of years (Daines and Heady, English and Heady, Larson et al., Meister and Nicol, Nicol and Heady, Timmons 1979a). These models are now being used to help the U.S. Department of Agriculture in its RCA monitoring and analysis and for related research. Since these models are documented elsewhere, we will forego detail and summarize only their general characteristics. The models are national and interregional in nature with 105–223 producing regions and 25–35 market regions and a linking transportation submodel. Each producing region includes 5–9 separate land classes with differential erodability and soil loss. (Irrigated regions have 10–18 land classes to allow for both irrigated and dryland crop possibilities.) Soil loss coefficients are defined for each crop or crop rotation, each conservation practice (contour, terrace, strip crop, etc.) and each tillage method (conventional moldboard, no till, conservation till, etc.) on each land class in each producing region under the varying climatic conditions prevailing. Restraints at different levels thus can be placed on soil loss per year for each land class in each producing region, with export possibilities determined accordingly. (Erosion restraints also can be established for regions, watersheds, or other physiographic entities.) One restraint level of particular relevance is the "t" tolerance level, the level of soil loss which agronomists estimate can occur if soil productivity is to be maintained (Wade and Heady). Alternatively, exports can be parameterized or set at different levels while soil loss per acre is measured by land classes within regions, or by regions, watersheds, river basins, etc. When used with an objective function of least-cost or competitive equilibrium, the models show the combination of crops, conservation practices, and tillage methods (i.e., the technology set) which will maintain a given level of soil loss at minimum cost while allowing a given level of exports to be attained. (As a long-run competitive equilibrium model, it also can show the most efficient combination of technologies for a given soil loss and export combination.) We have been in the process of deriving these possibilities for the U.S. Department of Agriculture in its RCA analysis and now are extending, respecifying and updating models for the 1985 RCA evaluation. These models not only can indicate the various sets of exports and soil loss levels which will allow sustenance of agricultural productivity over the long run (or the level of soil loss conforming to a given export level or vice versa) but also can estimate the cost of abating soil loss to specified levels and various export levels. They also can provide the basis for estimating the redistribution of income and asset values, especially among regions, associated with any specified or policy-induced soil loss and export sets.

We have recently constructed a five-land class, 105 producing-region model to focus on the relationship between soil loss and export levels. The land base (table 1) consists of 403 million acres of cropland estimated available in 1977 from the National Resource Inventory (U.S. Department of Agriculture). We project 26 million acres will be converted to nonagricultural uses by 2000. All but approximately 24 million acres would be available for the endogenous crops. The land classes are selected so that a range of erosion hazards and farming practices can be represented in the model with prime agricultural lands included in land classes 1 and 2, erosive but otherwise suitable lands in land classes 3 and 4 and most marginal lands incorporated in land class 5.

The range, pasture, forest, and other lands with high and moderate potential for conversion to cropland is incorporated in the model

Table 1. Projected 2000 Crop Land Base

	Region							
Item	North Atlantic	South Atlantic	North Central	Great Plains	South Central	North-west	South-west	Total
	(1,000 acres)							
Endogenous cropland:								
Land class 1	1,613	6,459	32,831	7,963	7,421	1,090	2,372	59,749
Land class 2	6,764	27,775	81,444	31,830	30,333	5,253	3,652	187,052
Land class 3	1,879	3,463	16,773	25,939	15,292	6,088	795	70,228
Land class 4	694	1,177	4,846	9,361	5,213	2,138	1,192	24,620
Land class 5	431	1,118	2,939	4,015	1,808	796	423	11,530
Total	11,380	39,993	138,834	79,108	60,067	15,364	8,434	353,180
High potential land:								
Land class 1	56	597	572	245	528	21	12	2,031
Land class 2	705	8,756	5,577	3,071	4,342	604	472	23,527
Land class 3	112	1,074	1,462	2,553	1,969	309	99	7,578
Land class 4	45	227	370	728	209	103	89	1,771
Land class 5	81	298	180	551	171	397	1,108	2,696
Total	999	10,952	8,161	7,148	7,219	1,434	1,690	37,603
Moderate potential land:								
Land class 1	94	360	360	132	316	5	8	1,269
Land class 2	2,214	14,963	8,989	5,006	8,375	993	1,155	41,695
Land class 3	736	4,517	3,770	7,144	7,423	649	363	24,602
Land class 4	308	1,748	1,794	3,536	2,486	543	717	11,132
Land class 5	500	2,281	1,212	3,548	1,109	968	1,781	11,399
Total	3,852	23,869	16,125	19,366	19,703	3,158	4,024	90,097

with appropriate conversion costs. Some authors (Amos and Timmons, Shulstad and May) have questioned whether as much as 127.7 million acres could actually be converted to cropland under any set of realistic conditions so we have duplicated our analysis with high potential land only and with both high and moderate potential land available for conversion. Except where noted otherwise below very similar patterns are evident in the results for both scenarios.

We project domestic consumption of endogenous crops in 2000 to be as follows: 199.1 million tons of feed grains (corn, sorghum, barley, and oats); 1,033 million bushels of wheat; 2,293 million bushels of soybeans; 7.7 million bales of cotton; 57.4 and 82.1 million tons of nonlegume and legume hay, respectively (from cropland only); and 109.4 million tons of silage. Projections of domestic consumption levels are relatively reliable so no attempt was made to parametize these numbers. Domestic demands do not include a component of grain for gasohol production nor is a biomass crop implicit in the land base. The overall effect of a significant "energy from agriculture" program would be similar in effect to increased exports but differ in detail.

Four different export levels in the year 2000 are examined. The lowest export level (level I) is a 50%, 53%, and 75% increase over historical exports over the period 1977–79 for feed grains, wheat, and soybeans, respectively. Export levels II, III, and IV are a 17, 67, and 117% increase, respectively, over the base export level. The most recently available NIRAP projection falls between export levels II and III. All export levels are feasible when both high and moderate potential land is available for conversion to cropland, but export level IV is not a feasible level when only high potential land is available for conversion.

An important result of our model is that far more extensive use is made of soil-conserving tillage methods and conservation practices than are currently practiced. No-till is practiced on between 50% and 60% of the land in all solutions and conservation till used on most of the remaining land. We feel that there are inherent advantages in the conservation till and no-till practices developed and being developed to make these the standard tillage methods of the future. Approximately 70% of the cropland is also selected for some conservation practice. Contour plowing is the most important, accounting for 50%–55% of total cropland. Strip cropping is relatively insignificant, accounting for around 4% in nearly all solutions. Terracing is used on 10% to 15% of the cropland with the amount of terracing increasing with exports.

Despite the extensive adoption of soil-con-

serving tillage methods and conservation practices, the tolerance levels for gross soil loss are exceeded on one or more land classes in a large portion of the producing regions even with low export levels. Tolerance levels are exceeded on some land classes throughout most of the North Atlantic and South Atlantic zones, a large portion of the north central and eastern part of the South Central and Great Plains zones. Tolerance levels also are exceeded in some of the most important agricultural areas in the Western states. The most notable change with increased exports is in the mid-continental states where tolerance levels are exceeded in a large number of producing regions only with highest export levels, although more marginal land is brought into production in all regions.

At low levels of export demand most of land class 5 is not used. Practices adopted on land classes 3 and 4 contribute most heavily to erosion. When export levels increase it becomes profitable to adopt practices which conserve soil and productivity on land classes 3 and 4: Soil loss per acre drops sharply for these land classes in many producing regions. The most marginal cropland in the existing land base, land class 5, is brought into use greatly exceeding the tolerance levels. The distribution of gross soil loss from cropland is very skewed in all solutions and becomes more skewed with increased exports. The number of acres in absolute terms exceeding the tolerance levels is not great in any solution and decreases with increased exports nationally and in all regions except for the South Atlantic, Northwest, and Southwest.

Conversion of potential cropland to cropland increases with each increase in the level of exports. Potential cropland is available in nearly all land classes in most producing regions, but the distribution of potential cropland is more skewed towards the erosive land classes. The land that is converted at lower levels of exports tends to be the least erosive. As export levels increase a larger proportion of the conversion is for land classes 3–5.

Gross soil loss increases with exports, but not dramatically at the national level. For example, gross soil loss increases by 21% when exports nearly double in moving from export level II to IV for the scenario with both high and moderate potential land available (table 2). With only high potential land available, soil loss decreases with increases in exports until the highest attainable levels of exports are reached where soil loss shoots up rapidly. Comparing the lowest level of exports with the highest, 1.88 and 0.24 tons of soil loss is incurred for each $100 (at constant prices) of increased exports for the scenario with high and moderate potential land conversion and the scenario with only high potential low conversion, respectively. But the trade-off at the national level conceals some of the most disturbing results. Soil loss in the western two zones more than doubles. There is a very large increase in soil loss both in absolute and in relative terms in the South Atlantic zone where soil profiles are relatively shallow and a high proportion of eroded soil finds its way into water courses and rivers.

Policy Implications and Focus

We expect to be able to provide increasingly refined quantitative estimates of the trade-offs or possibility frontier between exports, soil loss, and productivity coefficients before the

Table 2. Gross Soil Loss

	Zone							
Demand Levels	North Atlantic	South Atlantic	North Central	Great Plains	South Central	North-west	South-west	Total
	(million tons)							
Full land availability and moderate yields:								
II	24,468	162,769	299,648	234,507	205,554	21,829	12,043	960,819
III	30,093	198,124	284,156	260,169	215,795	29,665	15,743	1,033,745
IV	26,053	251,577	319,100	282,892	221,783	55,480	39,294	1,196,179
High potential land and moderate yields:								
I	23,108	155,189	329,298	212,434	178,281	19,768	11,342	929,420
II	24,644	180,476	259,316	230,541	171,072	27,488	12,271	905,811
III	18,254	210,508	265,008	208,278	180,578	45,640	16,269	944,534

1985 RCA assessment. However, we believe that those already generated provide a relevant basis for policy based on these normative estimates which indicate future potential. Some policy directions become fairly obvious. Society could, of course, decide to "continue all-out export efforts while domestic productivity goes down the tube." We doubt, however, that society should or will do so over the long run.

If society selects a mix of exports, technologies, and soil losses which maintain agricultural productivity and a favorable environment, it could use several approaches. One would be to attempt to set export limits (quotas, embargo limits, etc.) at levels which are consistent with a soil loss level, under appropriate technology, which maintains soil erosion and agricultural productivity at the desired level. For example, a dictum could be announced that exports above some level are to be embargoed. But a policy of this sort would be clumsy to administer (and could imply a farm income maintenance program due to reduced commodity prices). Exports also could be taxed for similar purposes. An upper limit or tax on exports also would be difficult to implement with respect to the most erosive soils. For example, highly erosive lands near the point of export might be planted to corn, soybeans, cotton, and similar row crops while level lands elsewhere were planted to close-grown crops and forages. Export controls would in no way relate to or restrain the type of conservation practices, tillage methods, or other technologies which relate to erosion and chemical run-off and, as our results indicate, would likely not be fully effective in protecting agricultural productivity. Hence, rather than to use export levels as a means to direct land use and erosion control or environmentally related technologies, the causal direction might best be in the opposite direction.

Supposing that there is some combination of quantitatively optimal levels of exports and soil conservation technology, then the cost (i.e., opportunity cost) of not controlling erosion should be sufficiently high that it eventually limits production and export levels—supposedly through a set of price mechanisms which encourage soil-conserving land use and technologies and thus increases commodity prices to the needed level in limiting exports to maintain long-run agricultural productivity. The prices (subsidies or taxes) could be related to specific conservation practices, tillage methods, and land use technologies which do restrain erosion (and perhaps chemical run-off) to goal levels. To tie the price (i.e., tax or subsidy) of erosion control to the particular practice and land class would be most practical in implementation and in getting erosion control where it is most needed in terms of (*a*) rates of soil erosion, and (*b*) the productivity of the land classes and locations to be conserved (Daines and Heady). One variant of this approach would be to institute an export "check-off" to fund such a program, perhaps adding to the rationale and political appeal.

Numerous other policy means could be used to attain sets of export and soil loss rates which would conform with a socially determined goal or optimum. Conforming soil loss levels (such as tons per annum, *t*-levels, etc.) could be established, then farmers could be penalized (fined, jailed, taxed, etc.) for soil losses above these levels. Policy of this nature is attractive from two perspectives: effective agricultural productivity is most genuinely protected; large reductions in soil loss would result (recall the skewed distribution of soil loss) and thus a substantial enhancement of environmental quality. However, this instrument would have low political acceptance and would entail other implementation complexities.

Drawing production and export levels down to conform with maintenance of long-run agricultural productivity (or the level which is determined to be socially and economically optimal via appropriate intergeneration expression of time preference or other criteria) would be expected to increase total market value of sales, and likely net income of farming, since most price elasticities of demand are less than unity. This growth in income through the market per se would be unlikely to result in an equitable redistribution of farming returns. Farmers on level land would have no conservation investment and could even cultivate their land more intensely; farmers on erosive soils could be faced with both greater investments in appropriate machinery and land preparation and reduced output from a less intensive agriculture. A system of practice subsidies or incentives (i.e., cost sharing, cross-compliance, etc.) would be needed to restore equity, as well as attain conservation goals, if unanimous consent were approached in the optimum mix of exports and soil erosion abatement.

Institutional and Other Forces Apart from Markets

The enhancement of markets through exports, coupled with inflation as summarized earlier, can have important impacts on land use and potential land productivity. Not every land class in each location is faced with an immediate precipice of yield declines. Erosion can proceed for some time in areas of deep soils before productivity declines will be experienced or will not be offset by advanced technologies. While they are greatly improving knowledge, agronomists are not in complete certainty and agreement on the rate of soil formation, vis-à-vis, rates of erosion or land deterioration. But a policy based on "t"-values may be desired until greater certainty in knowledge is attained. It would seem unwise for a society to let a major portion of its land erode down to the last two inches of soil useful in productivity. It thus is important that policies with respect to exports be integrated with those in respect to soil erosion, resource conservation, and environmental considerations.

In making this statement, we are, of course, aware that it is not alone the thrust of market forces and prices which cause exploitation of agricultural resources. Favorable price prospects over time can even place a premium on resource conservation and investment in it for some land resource groups. Frequently, it is not markets and prices per se which cause an accelerated use of stock resources such as groundwater or an exploitive use of land. The institutions and related conditions prevailing in agriculture and surrounding the market can do so. Examples include tenure systems and uncertainty of tenants' returns from conservation investment over time, the supply, terms and repayment schedule of credit, the age and immediate planning horizon of the farm operator or land owner, the paucity of information available to farmers, and others. There also are cases in which profitable conservation practices are not used because the farm operator or land owner is unaware of the level of return. In other cases, conservation practices are adopted with a distributed lag because farmers contrast them to customary practices (e.g., clean-plowed fields with no trash compared to residue-covered land). Where these voids exist, when conservation practices otherwise would be economic to the individual society, appropriate policy means or institutional change is needed to eliminate them.

Toward a U.S. Agricultural Export Policy for the 1980s: Discussion

Eric Monke

Sarris and Schmitz suggest that increases in exports are not likely to benefit U.S. agriculture, and that "production may have to be curtailed—at least in the short run—for optimal pricing to be achieved . . . ." Their argument has three principal components. First, agricultural growth is likely to depend heavily on research and development, and further expenditures in this area are asserted to have a deleterious impact on producer incomes. Second, U.S. agricultural trade is dominated by cartels, and increased production leads only to increased purchasing power for importing nations. Finally, increased participation in world markets creates increased price instability, and further reduces producer welfare. This discussion argues that none of the authors' conclusions in these areas are justified, and that continued growth in exports is likely to offer substantial benefits for the U.S. agricultural sector.

Research and development (R&D) expenditures are asserted to have a deleterious impact on producer incomes if such expenditures cause the supply curve to shift outward and become more elastic in the face of a fixed world demand schedule. Even if these supply-demand conditions were accurate, the conclusion suffers from a myopic view of the impact of R&D expenditure. Technological change frees resources to produce goods in other sectors of the economy, and can thus be regarded as a complement to capital accumulation in the process of economic growth. Indeed, some authors suggest that R&D is no more than a special form of capital accumulation (Jorgensen and Griliches). The key point is that the induced shifts in the industry supply curve give no indication of the changes in returns to individual factors of production. The reason is that technological change implies new input combinations, and declines in total industry revenues do not necessarily imply declines in the returns to individual factors or to the total factors employed in an industry. Admittedly, technical change can cause difficulties. Unemployment may result if aggregate demand is not increasing, and adjustment difficulties occur for resources committed to now inefficient technologies. These problems are short run rather than chronic in nature, however, and do not require an economy to restrain R&D and forego the benefits of economic growth.

Market power of importers is a second reason for U.S. policy makers to avoid expansion of U.S. exports. Tariff policies, implemented in wheat importing countries, for example, are asserted to benefit importers because "(domestic) producer gains plus the tariff revenue more than offset the consumption losses" of a tariff. Such evidence cannot justify the above conclusion. Tariff revenues are intracountry transfers from consumers to the government, and welfare increases from such transfers are dependent on empirically undefinable social welfare functions. The gains of domestic wheat producers are not gains at all when viewed in a general equilibrium context, as wheat tariffs attract resources which were more profitable when world prices prevailed for all commodities. When a country cannot influence world terms of trade, production income is maximized at world prices and can only decrease when resources are diverted into different production activities via tariffs.

Increases in importing country welfare thus depend on the ability to influence the terms of trade with the U.S. and other exporters. Since each importing country buys only a small share of world imports, establishment of the optimum tariff (the reciprocal of the price elasticity of export supply) requires a cartel in which individual country objectives are subjugated to group cooperation. Grains would appear as one of the least attractive commodities

The author is an assistant professor, Department of Agricultural Economics, University of Arizona.

for such an arrangement. The importance of imports in domestic food policies of many developing countries and the diverse set of countries involved in grain importation renders implausible the prospect of collusive action. Furthermore, it has not yet been shown that world prices of any principal export products are lower under current conditions than under free trade. In the case of rice, for example, the prevalence of government policies which tax domestic production and subsidize domestic consumption suggest an excessive reliance on world markets, and world prices which are higher than their free-trade levels (Falcon and Monke).

A third concern of Sarris and Schmitz is that increased exports will lead to price instability. In lieu of empirical evidence, a supply-demand model is developed and parameter values are hypothesized to support their conclusion. The first hypothesis is that the price elasticity of developing country demand is almost equal to that of U.S. domestic demand ($\gamma/B \simeq 1$). At the consumer level, this hypothesis is totally implausible because of the difference in income levels and the importance of processing costs in U.S. food grain consumption. Even if government intervention on behalf of developing country consumers reduced foreign demand elasticities, such values could still be much larger than U.S. consumer demand elasticities. The second hypothesis is that world export demand fluctuates more than domestic supply, so that $\sigma_u/\sigma_w < 1$. But, given the role of weather in output variation, the reverse result seems more plausible. Because weather varies among geographic regions at any given time, variability should decrease as geographical area expands ($\sigma_u/\sigma_w > 1$). Table 3 of the Sarris-Schmitz paper shows that for larger values of γ/β or σ_u/σ_w, price stability is increased by a reliance on world markets.

Even if increases in the relative importance of exports did lead to increased price instability, it does not follow that U.S. producer welfare is diminished. Empirical evidence (Falcon and Monke, Peck and Gray) suggests grain exporters may gain from price instability, since the export demand curve appears inelastic with respect to price increases and elastic with respect to price decreases. Government intervention on behalf of domestic consumers in developing countries and quota or variable levy policies in many developed countries create conditions whereby consumer demand is insensitive to world price changes. Elastic response to price declines may be caused partly by the emergence of additional end uses, such as animal feeds. Probably more important, however, is the behavior of commodity inventories. Peck and Gray's analysis of the demand for U.S. wheat inventories suggests a demand for grain which becomes almost infinitely elastic once the margin between current and futures prices reaches a certain magnitude. Part of the reason for the willingness of the market to encourage stock accumulation may be that yields are negatively skewed rather than normally distributed about their mean level. This phenomenon implies that production shortfalls and high price regimes are more probable than production surpluses and low prices.

Finally, Sarris and Schmitz suggest that the growth in world demand for grains is likely to slow or stop altogether, due to limited purchasing power in developing countries and the "rising agricultural protectionism in the major developed importing countries." If world demand is truly fixed, efforts to expand U.S. exports will clearly diminish world prices. There are a number of reasons to doubt such a stagnation in export demand and prices. First, even if per capita developing country incomes do not change, aggregate national income will increase because of population growth. Furthermore, positive rates of per capita income growth appear likely in at least some developing countries, such as OPEC and China. This small group comprises one-third of the population of the developing world. Potential demand increases also appear likely in the USSR and the Eastern Bloc countries, where ration programs have constrained meat consumption at levels well below those which prevail in other countries with similar incomes. The FAO projections cited by Sarris and Schmitz suggest a major decline in import demand from these regions over the 1975–85 period. On the basis of current trends, these projections appear erroneous. Finally, the author's evidence for increased agricultural protectionism among the developed countries consists solely of observed increases in ad valorem tariff equivalents in the EEC. These increases, however, are the result of falling world prices rather than changes in EEC prices and thus do not imply a negative impact on U.S. export demand. In sum, the potential sources of increased demand appear numerous enough to warrant at least a dose of the "unfettered optimism" so disdained by Sarris and Schmitz.

Interrelationship among Export Markets, Resource Conservation, and Agricultural Productivity: Discussion

Herbert H. Stoevener

The main body of the paper by Heady and Short consists of a brief description of the models and their application to deriving trade-offs between agricultural output (export levels) and soil losses. These models are based on the ones developed at Iowa State University over many years. It is impossible for the authors to describe these models in detail for us during this discussion. The basic model used in this application consists of 105 producing regions and contains at least 5 land classes in each region. Soil loss coefficients are specified for each crop or crop rotation, each conservation practice and tillage method, for each land class in each region, apparently taking varying climatic conditions into account as well. From such a model a large number of variables can be analyzed with a good deal of specificity depending on the chosen objective function and constraints set.

Four different export levels are assumed for the year 2000, with no provision for gasohol production in domestic demand. I could not follow the description of these demand scenarios from the copy of the manuscript available to me. Apparently these projections fall on both sides of another recent independently derived projection of export demands.

I found the reported results interesting and instructive. They are not always what I would have expected. With increased export demands, the application of conservation practices is predicted to increase sharply, even on land which is already in production. This is inconsistent with the expectation of many that farmers are led "to farm the land like hell."

In spite of the widespread adoption of conservation practices, tolerance levels for gross soil loss are exceeded in a large portion of the producing regions even at low export levels. And, while gross soil loss increases with exports, though not dramatically, at the national level, the "number of acres in absolute terms exceeding the tolerance levels is not great in any solution and decreases with increased exports nationally and in all regions except" four (p. 12).

Anyone thinking about these results for a moment can easily develop a rationale why they may have been obtained. It is about this aspect of the paper that I would have liked to have seen a bit more detail. The authors will know from the experimentation with their models to what relationships these important results were most sensitive. A discussion of the results in the light of this information would have been very useful, especially from a policy standpoint. More information is necessary to understand the projected increase in conservation practices. What is it that triggers a change from the current status? It is the strength of these very specific models to be capable of providing these kinds of insights.

Similarly, there appears to be a great difference in resulting levels of soil erosion by regions as exports increase. Again, it would be instructive to know what accounts for these. Is it the physical characteristics outside the flattest part of the Corn Belt which do not tolerate any significant increase in crop production without major soil losses? Or is it the nature of export demands with higher export product prices caused by transportation cost differentials which exacerbate farming system changes in hilly regions closer to major seaports?

The Iowa State-developed models are part of the major inputs which the agricultural economics profession is making to the public debate on conservation policy. The models are sufficiently complex that it is difficult for any outsider to undertake their empirical evaluation. Perhaps this suggests that when presen-

---

The author is a professor and Head, Department of Agricultural Economics, Virginia Polytechnic Institute and State University.

tations like this one are made to professional audiences, somewhat greater emphasis should be given to the analytical procedures when discussing the results obtained.

There is, of course, a limit on how much material can be presented in a conference paper of this type. But given my preferences, much of what was presented in the introduction (first six pages) could have been deleted. Many of the issues raised are common knowledge. The authors mentioned the implications for future farmer welfare of having a long string of growing future incomes already capitalized into land values. They mention inflationary expectations. For purposes of export and conservation policy it would be important to know which components of the returns to land ownership are due to agricultural use and which stem from inflation. However, this is a thorny issue. It is being addressed in a forthcoming paper by Castle and Hoch.

As far as conservation policy is concerned, Heady and Short appear to opt for a system of subsidies or taxes related to specific conservation practices, perhaps combined with an export "check-off" system to fund a subsidy scheme. Many of us, having studied this subject much less than the authors, would also find this proposal attractive. Again, it would have been nice if the authors had related this and the remaining policy discussion more closely to the analytical work. As I read the paper for the third time, I was struck by the lack of strong connections between the policy issues raised in the introductory pages, the final policy section, and the empirical analysis. The latter appears to be a much richer source for drawing out policy implications than was utilized in this paper.

I would like to make one final point about the general discussion of agricultural export policy which was touched upon in the paper by Sarris and Schmitz. Many of us in the agricultural community point with pride to the accomplishments of this sector in allowing for the large increase in exports that we have witnessed. One should recognize, however, that this is not a unique phenomenon in the national and international economy. While U.S. agricultural exports have risen rapidly (from 11.4% of farm cash receipts in the 1950s to 29.1% in 1980), their proportion of all U.S. exports has remained relatively constant during the post-war period and is considerably less than it was during the 1930s (CEA, p. 117). Exports as a percentage of gross national product (GNP) fell generally into the 4%–6% range. This changed during the early 1970s. In 1979 exports comprised nearly 11% of GNP (CEA, p. 203). Furthermore, on a global scale growth rates in agricultural trade have outpaced growth rates in agricultural productivity roughly by a factor of two between 1950 and 1980 (USDA, p. 4). When raising policy issues about U.S. agricultural exports, it is important to keep in mind that the subject of our concern is only one aspect of a growing internationalization of our production and consumption systems.

Changing Delivery Systems for Agricultural Extension
(John E. Ikerd, Oklahoma State University, Presiding)

Extension Program Delivery—Past, Present, and Future: An Overview

R. J. Hildreth and Walter J. Armbruster

The 1914 Smith-Lever Act, which launched extension education, has been amended frequently and was rewritten in 1953. However, its statement of basic purpose has remained the same: "to aid the diffusion among the people of the United States useful and practical information on the subjects relating to agricultural and home economics and to encourage the application of the same." An underlying though unstated purpose of this diffusion of information was to help bring about changes in behavior and in the economic and social environment designed to promote well-being. In other words, the extension purpose is to foster change in society—i.e., change by individuals, households, firms, and governments.

Development of Extension Delivery Methods

The land grant university and the extension service were distinctive American inventions (Chin and Benne). Extension was launched to deliver new applied knowledge to farm and rural people in the United States and to transmit their interests to the land grant university research community. That linkage continues to be the role of extension education, though significant changes in the audiences and environment in which extension operates continue.

The extension delivery methods adopted following the passage of the Smith-Lever Act relied on an approach whereby the learner observes a demonstration or tries out an activity. According to Baker, the demonstration form of education was developed by Dr. Seaman A. Knapp of the U.S. Department of Agriculture (USDA) Bureau of Plant Industry, who established the first farm demonstration at Terrell, Texas, in 1903. Knapp believed that though farmers would not apply methods successfully used in research, they would readily follow successful operations of a neighboring farm. Other demonstration programs were developed in Texas, Louisiana, and Arkansas in the early 1900s. The first county agent position was established in Smith Co., Texas, in 1906. Simultaneously, the northern states instituted county demonstration work based on farm management surveys to discover the practices of successful farmers. While Knapp distrusted college professors, the northern states' county demonstration agents were mostly college trained and worked in close cooperation with the state colleges and farm organizations.

Thus, while different philosophies about extension program delivery methods existed even before the passage of the Smith-Lever Act, the demonstration approach was widely adopted. It did not have a systematic teaching focus, but rather one of learning by the farmer observing a situation similar to his own.

Extension Delivery Today

In its early history, cooperative extension's role appeared straightforward and limited. Extension was the organization best equipped to attack informal educational problems of production agriculture and rural living. There was a close interrelationship of farmers and rural residents with extension.

Changing Extension Role in Traditional Areas

Since the introduction of extension, there have been dramatic changes in agricultural production, agricultural marketing, and the rural communities which extension serves.

R. J. Hildreth and Walter J. Armbruster are managing director and associate managing director, respectively, The Farm Foundation.

The authors wish to acknowledge helpful suggestions from Elizabeth Bolton, James Bonnen, John Ikerd, and James Shaffer.

Concurrent with increasing productivity, structural changes throughout the farm production, food processing, and marketing system have changed the role of extension in farmers' production and marketing decisions.

Production supply firms and agricultural cooperatives provide field men who help farmers with technical information that in earlier days had come primarily or exclusively through extension agents from land grant university research findings. An increasing number of agricultural consultants provide similar services. The input supply companies have done additional research, often drawing upon the basic research done at the university. They develop new products and are in the forefront of knowledge about actual farm application. While this has not completely eliminated the role of county agents, it has certainly supplemented and partially replaced them.

As the agricultural marketing system evolved over time, most central wholesale markets which received products shipped from long distances have been replaced. Now chain store buyers and food-processing firms have buying representatives dealing directly with farmers, feedlots, etc., or buying through local country auctions. An increasing contact between representatives of the purchasing entity and the producers is the result. Thus, the role of extension marketing has shifted more to helping farmers develop overall marketing strategies and providing educational programs related to marketing institutions and policy. That activity has become much more important in recent years with changes in government programs and the opening up of world trade in major commodities, with consequent fluctuation in prices.

New Subject Matter and Clientele

Hildreth has pointed out some of the changes faced by extension in recent years. Extension is no longer confined to agriculture and rural life. Expertise to deal effectively with the problems incurred in the new areas is not always available on the campuses of land grant universities and demands a multicollege approach and cooperation with off-campus resources. Extension is not the sole provider of educational programs in the new fields, and in some, may be a relatively minor participant, e.g., urban youth and community resource development activities.

Serving the new areas and audiences has created stresses on extension. First, sufficiently increased resources have often not accompanied the new demands. Shifting resources from established programs has been painful to many of extension's traditional clients who jealously guard "their" programs. Second, the diversity of the clients for traditional programs has increased a great deal. Hobby farmers, part-time farmers, small farmers, subsistence farmers, and commercial farmers may all need farm management programs—but of varying characteristics. Third, delivery mechanisms such as meetings and publications are less useful for the new audiences which include persons with low education and income levels, just as they were not useful when most farmers had low education and income. And competing time demands, more glamorous delivery mechanisms, and audience heterogeneity make them less effective. Fourth, topics for educational programs that were once innocuous may now be quite controversial. For example, the use of insecticides as a means of increasing productivity may be questioned by organic gardeners and farmers or a policy to increase farm income may be questioned by consumer groups.

Changing Delivery Methods

While the major principles of extension programming—involving students in program development, presenting education in an informal setting, and focusing on practical information—remain the same, some new delivery techniques have developed.

For example, a variety of communications devices are being used. Telephone messages accessed by toll-free telephone lines provide cost-effective delivery for relatively simple practices. And there is growing use of computers, video tapes, and electronic networks, some interactive.

Some very productive delivery methods have evolved using salaried aides and volunteer agents. Salaried aides from the local community have been successfully used to deliver nutrition education to low income families and small farm programs. The idea of volunteer leaders developed in 4-H programs has been applied in using master gardeners to deliver information about gardening, primarily to urban audiences. These lower paid personnel, locally based to reduce travel costs, greatly expand extension's delivery capability for the same budget.

The identification and education of community leaders is used widely in community resource development extension programs. The pilot leadership development programs supported by the Kellogg Foundation have demonstrated their worth and are spreading among the states. Extension Homemakers organized at national, state, and county levels provide leadership development. A Kellogg funded program is currently developing public policy education program delivery capability through Extension Homemakers in the western states. The 4-H and Homemakers organizations, sponsored by the Cooperative Extension Service, develop leadership through volunteer educational and service projects benefiting the members and community. These volunteer programs expand extension's delivery capability without the direct cost of funding salaries for program delivery.

Another set of organizations which enhance program delivery capability are farm management associations employing paid field staff to deliver farm management programs.

Effectiveness of Extension

Given the changes and pressures, it is appropriate to look at what evidence exists about the value of extension in meeting the needs of today's society. If value can be measured in terms of the effect of extension on agricultural productivity, there are several recent economic studies that may shed some light. Generally these studies combine research and extension, and have found that the USDA and land grant university research and extension efforts have made a major contribution to the rate of technical change in agriculture.

Most studies place the internal rate of return in the United States between 25% and 50% to investments in research and education (Sim and Gardner). Araji estimated the internal rates of return for research investment in the western region related to selected commodities. His analysis identified over 50% of the results as being associated with input from extension. Peterson and Hayami suggest that the public investments in research and extension are responsible for as much growth in American agriculture as are changes in the quality of inputs and economies of scale in farm production. The 1980 evaluation of extension cites Evenson's statement that the public sector of agricultural research and extension and the level of education of farmers together may account for nearly 50% of agricultural productivity increase between 1948 and 1979 (USDA). Huffman recently estimated productivity differences on black and white operator farms in four southern states from 1964 data, when two separate extension services existed. He concluded that much of the lower productivity for black farmers was explained by the lower level of schooling and extension education available to them compared to white farmers.

So, if the methodological approaches of the studies cited are accepted, a minimum conclusion is that there is a positive, relatively high rate of return to society's investment in research and extension dealing with agricultural production and marketing. The studies cited above suggest that extension education is a good investment, but they do not give much insight into the possibilities for improving the value of extension through changes in program delivery.

Extension Delivery Tomorrow

What needs to be taken into account in thinking about assuring meaningful extension delivery for the future? And what changes are needed to keep extension delivery viable, efficient, and progressive? These are difficult but important questions which are only introduced in the following sections.

Implications of the Changing Farm Typology

The best known characteristics of the farm sector are that the average farm size has increased and the total number of farms has declined. An ESCS study projects that by the year 2000 farms probably will be arranged in a bimodal distribution with a large proportion of small farms, ever increasing proportion of large farms, and a declining proportion of medium size farms (Lin, Koffman and Penn). The implications for extension programs of this bimodal distribution are very significant. The traditional audience for extension programming comes from the middle size farmers who are not so large that they use direct access to researchers to obtain information. Extension has had a difficult time directly reaching the small and part-time farmers, the most numerous category.

The phenomenon of the large or knowledgeable farmers obtaining information directly

from experiment stations and other scientific sources rather than from county extension agents is described by Havelock and Benne as "by-pass." Extension must either better prepare itself to deal on a timely and informative basis with the large or knowledgeable producers or recognize that theirs is a minor role with that segment of agricultural producers and concentrate on the remaining segments of the producers.

The latter option is embraced by the recent ESCOP report which proposed as a strategy for public research and extension: Scale neutral research and extension should be emphasized; special measures should be developed to help the moderate size farm through programs dealing with financial, marketing, and production management; and an overall package of assistance, especially in dealing with problems of poverty and underemployment, should be provided to assist those associated with small farms.

Improving Extension Delivery Efficiency

Adjustments will be necessary to maintain a clientele among farmers. But other changes also are called for if extension is to weather the increasing demands for accountability. Boone, Dolan, and Shearon argue that funding for educational programs is positively related to demonstrated efficiency and effectiveness. Rather than follow the same objectives and methods year after year, extension must build in system renewal processes to remain a viable educational force.

Extension is facing increasing demands for improved efficiency of program delivery from both the input and output sides of the extension production function. Increasing amounts of knowledge to be extended, transportation costs and personnel costs are forces from the input side. The growing complexity of decision making in agriculture, the growing specialization of agriculture, and policy development are forces from the output side.

Siegfried and Fels, reviewing research in teaching college economics, report that programmed instruction can accomplish economics learning in a shorter length of time, and self-pacing of learning has a significant contribution to make to economics education. While the results above are for the classroom, programmed instruction and self-pacing of learning may work better for extension programs with more highly motivated participants than for classroom students.

This brief analysis leads to consideration of certain alternatives for the improvement of extension programming efficiency. The selection of audiences with higher human capital for a given extension program could lead to efficiency gains. This could be accomplished by better targeting programs to specific clientele groups that would consist of individuals with a better knowledge background at the start. The use of extension teachers with higher human capital could also lead to efficiency gains. This can be achieved through increased training of field staff or the use of more specialists, a point to be discussed later. There are a number of opportunities to improve utilization rates of both faculty and clients. These run a gambit including group meetings as opposed to individual consultations, use of mass media, and electronic transmission of information.

Increasing Extension Specialization

The changing clientele for extension and the increasingly technical knowledge to be delivered to them may call for more specialization. But the likelihood of significant expansion of state specialist ranks is slim. However, there are other ways of developing specialists that may be cost efficient for the extension system.

The development of national or regional specialists offers some potential. The rural crime center at Ohio State is essentially serving the role of a U.S. specialist. Several proposals have been brought forward in the past couple of years for development of a regional or national specialist in transportation economics. The Western Livestock Marketing Project performs a specialist function for the entire western United States, with some spillover into other regions.

The many issues and concerns which cross state and even regional boundaries argue for additional regional or national specialists. Developing programs using regional specialists would enhance the work in computer applications to farm management and marketing and using computer networks as transmitters of timely information. The recent work in electronic marketing has the potential to go well beyond state boundaries in some cases. Joint funding of such regional or national specialists would be a much more efficient delivery method than having personnel who are not familiar with the topic attempting to deliver educational programs related to it.

Another way of achieving cost efficient

specialization might be to have local or area agents who have particular interest and expertise act as a state or even regional specialist. This may become more feasible as more highly trained individuals are available in county and area slots.

Electronic Program Delivery

The use of computers and electronic networks is growing in farm management and marketing programs. The technology has also been applied in CRD and public policy programs and its use will likely grow in these programs.

To realize the full potential of computers and electronic networks hardware, software must be developed and local agents trained. Cooperation among states in developing software is growing, but more is needed. Local agents can increase their output and educational capabilities by using this technology. Thus, training and involvement of agents by specialists will be productive as the use of the technology grows.

The technology creates ability to transmit large amounts of information and provide the opportunity for individual decision analysis, both exciting prospects. However, there is danger that both the client and extension worker will overlook the use of the technology to provide learning situations. Extension cannot, nor should it seek to, maintain a monopoly on electronic delivery of information and individual decision analysis services. Extension must provide educational opportunities utilizing electronic delivery to allow its clientele to better utilize the information and analysis capacity of computers and electronic networks.

Implications for Extension Economists

The above discussion leads to some speculation about the implications for agricultural economists conducting extension education programs in coming years. Decisions and events off the farm may be more important than decisions and events on the farm in terms of their impact on the well-being of farmers and consumers. Public policy and community resource development are not only important for main street businesses, consumers, and rural residents, but also for farmers (Wise). ment and delivery for the wide range of students who want and need their educational services?

Agricultural economists have a role to play not only in the production and marketing of food and agricultural products but also in activities related to concerns about food and agricultural policy, community development, rural government finance, conservation, environmental and water policy, transportation, etc. It will be important for extension programs developed by agricultural economists to focus ahead to anticipate expected changes in the composition and structure of the agricultural production sector, the agricultural marketing sector, consumer interests, and concerns of rural communities, community leaders, and other institutions dealing with food, agricultural, and rural communities.

Extension is a link between research and the users of knowledge. Traffic flows both ways over the linkage. The extension professional thus needs to be able to adapt the new knowledge developed by research to the educational needs of the user, as well as communicate the needs of the user for new knowledge to the researcher. The scholarship requirements to achieve these tasks are large. The extension professional often needs to be able to touch the abstract and the concrete in the same flight of thought. In many ways, more scholarship is required here than is required to develop new knowledge. The economist working in extension cannot be divorced from new developments in economics any more than from new developments in farming, marketing, or public policy. The extension professional must take an active role in the AAEA, just as he must maintain his contacts with the managers of the firms or organizations who constitute his students.

The challenges presented to extension by changing clientele, program needs, and delivery innovations must be dealt with in a mode of increasing efficiency. Creativity and imagination are needed to be an economist filling the role of an agent of change through extension education where the needs will continue growing faster than funds.

Araji, A. A. "Returns to Public Investment in Agricultural Research and Extension in the Western Region."

delivery system. With the backup of state specialists, the county agent can meet the educational needs of the small- and medium-size farmers. Demonstrations, short courses, tours, and publications remain as effective means for delivering information to these audiences.

If resources were more abundant, area specialists would be the preferred means of delivering educational programs to commercial farmers. But the harsh reality is that extension will have to operate with less. Frequently, the county agent will have to be the primary local contact for commercial farmers.

The new developments in electronic communication, individualized learning, data storage, retrieval, and analysis offer the potential of greatly increasing the capacity of the county agent to assist the commercial farmer with more complex and sophisticated problems.

The burden of the responsibility for orienting the new county agent and keeping all agents competent in subject matter will continue to rest on the state extension specialists. Departments in the college of agriculture will be challenged to find the resources and expertise to keep abreast of the fast moving developments in the technology and structure of agriculture.

Opportunities for innovative program development between extension and other groups need to be explored vigorously. Commercial farmers can and will pay for educational service activities. Some examples are the farm business management services, computer-assisted decision programs, marketing price data, and outlook information.

Extension is not the only source of agricultural information available to farmers and in some areas it is not the most important. Extension must reassess its real strengths and make adjustments to assure a high quality program. This could mean dropping some programs completely, teaming up with private business to find sufficient resources to impact on a problem, and cooperate with other agencies to assure maximum return from the investment of public funds.

The unique educational concept of extension is as valid today as it was in Seaman Knapp's day. Program development must begin with local people. Research is the key to solving problems and extension's educational programs bring about change—change in the capacity of people, change in quantity and quality of information, change in the speed and efficiency of knowledge transfer.

The extension teacher is crucial in this educational process. The individual must grow in technical competence while holding on to the mastery of program development and communication. In an age of rapid change and greater specialization, it is urgent that extension maintain a great degree of flexibility so programs can be adjusted to the changing needs of farmers and the rural communities.

The Computer—Extension's Delivery System of the Future

H. G. Diesslin

You can hardly pick up a farm magazine today without seeing stories on "Computers—Newest Farm Implements," or some such title. Major TV advertisements during the Super Bowl heralded the arrival of computers for the family farm. Salesmen are stumbling over each other with hardware to sell; when discussions about the accompanying software necessary to make the hardware useful are opened, the salesmen quickly change the subject.

Yet, looking ahead over the next decade or two, the arrival of the computer on the farm, with the vital software necessary, will be a significant—perhaps the most significant—technological innovation on the family farm during that period of time. The magnitude of its potential is difficult to behold and certainly defies description at this point in time. The major question remaining at the moment is: "When will the knowledge base of American agriculture—the land-grant universities and the U.S. Department of Agriculture (USDA)—turn their collective talents to building viable software to allow the computer to function on the American family farm?"

Robert C. Kramer, program director, W. K. Kellogg Foundation, makes the following predictions for 1990:

> Three-fourths of all the mid-size farmers in the United States in 1990 will utilize computers or programmable calculators in helping make management decisions on their farms. . . .
>
> Many of the farming operations will be computerized and by electronic controls the operations will be automated. . . .
>
> There will be intelligent terminals in 90 percent of the county extension offices in the United States. . . . Virtually all of the departments of the Colleges of Agriculture and Home Economics will have terminals and/or small computers. . . . U.S. agriculture probably has the honor of being the top industry in the United States where the end-users (farmers) know more about computer programs. . . . By 1990, the gap will widen. . . .

H. G. Diesslin is Director, Cooperative Extension Service, Purdue University.

> Computer marketing or electronic marketing will be commonplace in 1990. . . .
>
> Regional development and sharing of software, regional sharing of specialists and regional computer networking will be commonplace in 1990. . . .
>
> For extension personnel who pioneered in the agricultural computer field during the past two decades, there were frustrations and disappointments. It will take hard work and patience, but U.S. farmers and their families will benefit from computer programs developed by the land-grant system.

Extension's Delivery Systems

The demonstration technique innovated by Seaman Knapp ultimately catapulted into an institution called the extension service. This technique is still central to the institution, although it continually undergoes modification with changing times and technology.

Other delivery systems—though secondary to the demonstration—are significant vehicles in the educational mission of the extension service. Among them, the following warrant separate comment:

(*a*) The extension bulletin (call it what you want). It was free; in the early decades of the century, it constituted the rural library of America. No longer free in many states, and no longer a monopoly as an information source, it remains an important delivery system for extension education.

(*b*) Penalty mail, often referred to as "free mail." Through the decades this has been an important partner to the free publication. Since the early 1970s it has not been free; it costs the same as regular mail. The only thing uniquely representing its importance in our history is the symbol, the penalty mail eagle on the envelope. As we discuss this topic today, ECOP is considering allowing states to discard the symbol and move to stamps in the near future.

(*c*) The "meeting" throughout the year, but particularly throughout the winter months, is and remains central to the extension educa-

tional program. Though the meeting technique ebbs and flows with the state of the economy—high energy prices are momentarily of concern—it, like the demonstration, is central to the educational delivery system of cooperative extension.

The decade of the 1980s gives the cooperative extension services an opportunity to establish a new, significant delivery system, the computer. We dare not "pass"; further, we have an opportunity to reestablish our leadership in the mainstream of American agriculture. Thus, I have elected to concentrate my remarks on the Indiana extension experiment with the computer over the past five years.

The Story of FACTS

The background of FACTS, Fast Agricultural Communications Terminal System, begins when the Purdue University School of Agriculture, including the cooperative extension service, initiated its original adaptation to computers in the 1950s and 1960s. This involved the use of teletypes, "dumb terminals," in scattered counties and area offices in the cooperative extension service around the state. Interaction was possible through long distance calls to the Control Data Computer (6500) which served the entire university. This involved a long learning process, basically on the part of our farm management staff in the field. Other agents essentially did not know the computer existed and had no hands-on experience with it. There were problems at the computing center at the university; in many instances there were long waits with open long-distance lines and, obviously, considerable costs involved before programs were run. Further, this system was not capable of out-of-state use, like AGNET in Nebraska or TELPLAN at Michigan State University, because of the way the system was programmed. From the standpoint of extension, there were only two major departments in the school of agriculture that made much use of it—Agricultural Economics and Animal Sciences. Our faculty in the Agricultural Economics Department developed complex crop and financial models that could be run and interpreted by our specialists. The "Top Farmer" program was widely acclaimed throughout the Midwest. Animal Sciences used the system for least-cost ration formulation, judging results, carcass evaluation programs, and the like.

This system involved the scientist with ideas, a programmer to implement his ideas within the capability of the machine, and few other constraints. There was little compatibility from program to program and little transferability from scientist to scientist or agent without intensive training.

In the late 1960s and early 1970s, the Purdue agricultural complex moved into a new phase of computer technology. This was the adaptation of the "intelligent terminal" to agricultural research. Through a grant from the National Science Foundation, we established PROJECT MIRACLE (Multidisciplinary Integrated Research Activities in Complex Laboratory Environments) to serve the Indiana Agricultural Experiment Station research and service laboratories throughout the Purdue agricultural complex. This system at the present time encompasses 20 laboratories, 50 terminals, and more than 260 researchers. The research performed with MIRACLE support led to the development of information which has been incorporated with extension service teaching materials. It makes possible certain FACTS activities, for example, the collection of data from the National Weather Service which is now sent out daily to the FACTS terminals throughout the state. More important, PROJECT MIRACLE developed and provided a wealth of experience to personnel who would later become involved with the FACTS project.

This project, which originated in the Animal Sciences Department, was quickly adapted by physical science departments (their first experience in many instances with the use of computers). This system involved new instrumentation—the minicomputer at the source of the research—in the greenhouse, in the weather station, at the lab. In addition, it involved an intermediate intelligent terminal for data storage and processing along with an automatic linkup with the university computer center. Once the program was written and verified, this removed much of the human error in complex program solving. It allowed what I call "machine to machine" research to begin to develop. Further, it led to complex interdisciplinary research undertakings with important extension applications which have now followed.

MIRACLE gave us experience with intelligent, low-cost computers, and it gave many scientists an opportunity to learn the technology of their use. Extension applications be-

came apparent. Networking was in its infancy throughout the country, but the hardware requirements were now becoming available. With this background, staff capabilities were available at Purdue University to lead such a new program. Thus, we were ready to move forward with a proposal to the Kellogg Foundation for the joint venture we now call FACTS. Compared to the typical university grant venture, I would classify this as "high risk." The Kellogg Foundation was not easily convinced that they should be jointly involved in such an undertaking. They had pioneered computer work in the Cooperative Extension Service fifteen years earlier with Michigan State University in a program that led to TELFARM and TELPLAN. The proposal was approved after lengthy discussions and an intensive site visit that laid out the plans in some detail; thus, in August 1976, the FACTS program of the Indiana Cooperative Extension Service was initiated under the sponsorship of the W. K. Kellogg Foundation.

General Mission

The objective of the FACTS system is, basically, to identify those circumstances in which the unique capabilities of the computer enhance or improve the basic function of extension. In the initial phase for implementing FACTS, the following guidelines were established.

(*a*) In information communication, FACTS will be used in instances where speed and currency are of primary importance in making information useful. It is not to be used to replace the printed word, mail, or telephone for the general distribution of information.

(*b*) In memory applications, FACTS will be used for operational management situations in which large quantities of repetitive material are used, such as mailing lists, program enrollments, and instances where regular, periodic, minor updating of technical bulletins is necessary.

(*c*) In its problem-solving capacity, the potential use of the FACTS system far outreaches the resources available. In the immediate future, development priorities will concentrate on (i) those instances in which individualized data of the client is helpful to his decisionmaking; (ii) those situations in which the limited specialty resources either on the campus or in the field preclude effective personal teaching relations (thus, FACTS can be a true *extender* of scarce resources to great numbers of clientele with specialized problems); (iii) those situations in which there is a reasonable time of operation and simplicity of user input (The programs should also have broad and long-term use.); (iv) Those situations which are complex and require the interaction of several disciplines or specialties of campus staff, including other computers.

The Scorecard

The Indiana Cooperative Extension Service, through FACTS development during the past five years, now has intelligent terminals in 100% of its counties and 100% of its agricultural and home economics departments, all tied into a networking system by private telephone lines.

Compared to the typical university grant venture, FACTS would have to be classified as a very "high risk" undertaking. By the end of the fifth year, 31 August 1981, more than \$5.5 million will have been involved from three major sources—Kellogg Foundation, \$1.9 million; Purdue University \$1.6 million; and the County Cooperative Extension Services, \$2.1 million.

An undertaking of this magnitude impinged on all existing academic departments and the entire field staff. It involved formation of a whole new department—Ag Data Network—composed of nearly two dozen professionals to develop, implement, and operate the system. Yet, without the simultaneous development of software by the extension specialists and departmental programmers, there would be nothing to implement. Further, the user clientele—county extension staffs—who purchased the equipment were at risk with their support groups unless they had numerous, high-quality software programs for their local machines.

We currently have more than fifty software programs available at the county level throughout the state. We are bringing approximately two new programs out each month, and the quality of the software is now approaching our intended standards of excellence.

We faced a dilemma in putting this operation together. I describe it as integrating a complex highly structured component into a highly unstructured academic and field staff educational program, the cooperative extension service.

After several years of frustration—near chaos at times—it is nice to see "light at the end of the tunnel." Adding a subsidiary to the corporation is not easy. It if had been easy, it would have happened a long time ago somewhere in these United States. At this time, less than five years from inception, a fully integrated, intelligent computer network is now in place and operational.

Looking to the Future

With a computer in every county and area office and in our academic departments, can we service the educational opportunities of our extension clientele, the citizens of Indiana? Obviously not. These units just represent the "tip of the iceberg." To be used effectively, the computer ultimately must be located with the end user, on the farm, or in the home, for example. How do we move it from the extension office to the end user, and why?

Critical to successful agricultural computer programs is relevant software for problem solving. The knowledge generator for American agriculture is the Agriculture Experiment Station and the Cooperative Extension Service of each state in cooperation with the U.S. Department of Agriculture. Thus, these institutions must assume the responsibility of translating research and information into software packages applicable to family farms and related agricultural production and marketing institutions.

By making our computer programs available to all our clientele through our extension offices, we are now able to provide the same programs to the individual to use on his own computer, at his own expense of course. Under such an arrangement, we are not open to criticism for working with only a special sector of our agricultural clientele. Each state, and the nation, must face this major policy issue in a consistent manner through the Land Grant-USDA partnership.

Looking ahead, in Indiana, a possible second step is to make our software information and programs available to vocational agricultural departments that are financially able and ready to purchase compatible equipment in their high schools. This would serve both an educational function—giving high school students hands-on experience with computers—and problem-solving opportunities for the home farm.

The third step involves getting the computer on the farm itself, into the hands of the end user. This becomes possible when our software packages are of sufficient economic value to justify the purchase of farm computers. An agricultural computer association, similar to farm accounting and farm management associations common in the Corn Belt, is one form such an end-user group might adopt. Members would own their own equipment, including the central switching and computing center serving their association, and they would purchase their software packages from the land grant institution servicing their state. Related services would be purchased from other suppliers. Over time, some users would develop the capacity to write some of their own software programs.

By making all programs available through our extension offices, we can, without public antagonism, work with those who can afford their own and add a new dimension to the competitive efficiency of American agriculture. We look forward to a pilot effort, putting the computer on the farm, in the not too distant future in Indiana.

Policy Issues

Policy issues facing the adaptation of the computer to American agriculture are many and varied. A few that have surfaced as we struggled with FACTS over the past five years include:

(*a*) Do we all need to "reinvent the wheel" in order to get started? Our grant with Kellogg Foundation involved developing a prototype extension networking system with intelligent minicomputers. The networking system necessarily was developed from the ground up to make the system functional. The cost for developing the networking system alone will total close to $2 million before it is completed; and, more important than the monetary cost, it will take more than four years to accomplish. Does every state need to start from the beginning and invest this kind of time and money to put a system into operation?

States interested in establishing a network with compatible or near-compatible equipment can save two to three years startup time and much of the $2 million cost. As a prototype system, we stand ready to transfer our present technology to any extension service compatible system at comparatively nominal costs.

(*b*) Do we not have a right, perhaps an obligation, to share software? Software packages are expensive in the development stages. Whether or not to copyright our software was another major policy issue in Indiana. There seem to be as many copyright policies in existence as there are universities. We decided to copyright our programs and are currently doing so. We are doing it for the following reasons: to carry the university name and reputation with the programs developed; to give further credit to the "creators" or "developers" of the programs in the university review system; and to allow franchising in the commercial or private sector if the program has widespread appeal and proprietary value that should be protected for the university and inventor. The protection of a computer program itself through the copyright policy is of minimal value.

Our copyrights, signed by the creators and department heads and agreed to by the university, carry the following exclusion for each copyrighted program: "Permission is given to Purdue University for use of said materials in any non-commercial or educational activity including but not limited to the University relationship to and function in the cooperative Extension Service which would include cooperation with any other state cooperative Extension Service for non-commercial or educational purposes."

Thus, our programs are available for other cooperative extension services on the above terms at nominal costs. This remains true even where a private franchising agreement has been consummated.

(*c*) Can we establish and carry out documentation standards that allow program interchange at minimal cost? We have established standards and procedures for documentation that are unique before a program will be used in our FACTS system. The documentation is such that the program can be adapted to any computer system (of sufficient size) or language with very minimal effort. Such standards are not now present in our land grant universities or cooperative extension services.

(*d*) Can we arrange multistate programming in areas of similar agriculture—the Corn Belt or Great Plains, for example? Large land areas in the United States have common types of agriculture, e.g., the Corn Belt, the Lake States, and the Great Plains. The real scarcity in agricultural computer development is the number of scientists and specialists available to create relevant programs to make a viable system. If groups of states with common types of agriculture would develop compatible systems, each would have the best scientists' programs from all the states in the region. If we could implement the Midwest Plan Service or Swine Industry Handbook concept to computer programming, what a magnificent breakthrough this would be for our extension services, and, more important, our farm clientele across the nation. We need this sharing of development resources in Indiana today and stand ready to assist in any such undertaking.

The development of regional centers, such as the North Central Computer Institute, will allow us to address issues similar to these and find solutions mutually beneficial to our ultimate clientele.

Changing Delivery Systems for Agricultural Extension: Discussion

John Holt

Plaudits to the program planners as well as the authors of the three papers! The papers fit together into an interesting mosaic that points a direction for future extension delivery systems. My role is merely to highlight their inherent continuity, and to emphasize a point about where to concentrate limited extension resources as that direction is followed.

The papers should be read in order: Hildreth and Armbruster give an overview of how we got where we are that, happy surprise, is not boring. At least one-half day of any New Agents' Training Conference could be replaced by reading their one sentence gem: "The major principles of extension programming (are) involving students in program development, presenting education in an informal setting, and focusing on practical information." And they conclude with the central problem of the future: The need for delivery innovations "will continue growing faster than funds."

The casual reader may need reminding that the bulk of Hildreth and Armbruster's remarks apply primarily to county extension work. But Brown sharply separates his remarks about county, area, and state professionals. The "age-old" extension problem is one of program balance between selected audiences, along with developing the necessary staff competence. Brown's analysis rests on the same rails as the first paper: "The harsh reality is that extension will have to operate with less. . . . Extension must," according to Brown, "reassess its real strengths and make adjustments to assure a high-quality program. This could mean dropping some programs completely. . . ." The difficulty of doing so was plaintively sounded almost a decade ago by Sprott: "The typical Extension Service worker . . . seldom if ever discontinues doing any thing. Most Extension programs are taken on in addition to rather than in place of a current program" (p. 55).

Brown sagely observed that "The new developments in electronics communication, individualized learning, data storage, retrieval, and analysis offer the potential of greatly increasing the capacity of the county agent to assist the commercial farmer with more complex problems." The stage is set for Diesslin, who enthused that the arrival of the computer on the farm offers potential that "is difficult to behold." Surely, we can agree, and we can all fervently hope with him that with the computer, "we have an opportunity to reestablish our leadership in the mainstream of American agriculture." And those of us who do not have elaborate (or in some cases, even infantile) systems can be grateful to the Kellogg Foundation, to Purdue, to Oklahoma State, to Michigan State, and to those other pioneers in computer applications in agriculture from whom we can borrow.

Let no beginning state extension specialist ignore the guidelines that Diesslin lays out for implementing the FACTS system, particularly those dealing with using computers in their problem-solving capacity. Those guidelines could save years of floundering.

So the computer can save us. But how? The life raft is simply too small for all of extension's programs. Some tough choices must be made about the audiences that will be served. Some programs will have to be dropped: indeed the Florida legislature has mandated that some nonagriculture programs be dropped. Hildreth and Armbruster's notion of abandoning the large producers should be dropped, as should those ideas Brown emphasized from *A Time to Choose*. Concentrating on our comparative advantage means working with commercial agriculture, which made extension what it is (Holt, Pugh, Brant).

In the future, should not our response be like the popular girl at the country dance? She refused all new suitors with the words "No, I'll dance with who brung me here."

John Holt is assistant chairman for extension and farm management specialist, Food and Resource Economics Department, Institute of Food and Agricultural Sciences, University of Florida.

Changing Delivery Systems for Agricultural Extension: Discussion

Harlan Hughes

The three papers presented accurately describe (*a*) extension's philosophy and goals, (*b*) extension's staffing and expertise needs, and (*c*) Indiana's FACTS computerized delivery system. Although the papers presented by Hildreth and Armbruster, Brown, and Diesslin address different issues, they all perceive problems which impair the flow of research information to our clientele. The purpose of my discussion is to probe further into these problems and to suggest possible means for improving information delivery systems for extension.

Hildreth and Armbruster point out that extension is generally oriented toward the middle-size farms, which are shrinking in number and potential strength. They suggest extension may well forget about serving large producers. In my opinion, the survivability of the West's long-run extension programs hinge on gaining the support of the large producers. Their political support is much stronger than what the numbers indicate. These are the clientele that will speak out for (or against) extension in public hearings. Strong testimonials are going to be needed to keep extension's present resource base.

Hildreth and Armbruster state that "extension is a linkage between research and the users of knowledge." The complexity of many of today's research projects requires the extension specialist get involved early in the research phase. It is becoming more and more difficult for an extension specialist to use the results of a finished research project to serve his or her clientele. This, in my opinion, is the strongest support for joint extension/research appointments.

Brown argues that the potential for mounting successful extension programs rests more with in-service training than with recruiting more specifically trained county staff. Professional improvement programs are extension's primary investment in human capital; however, very few state extension services are making major investments in professional improvement programs. I believe extension staff, particularly agents, should spend at least thirty work days a year in professional improvement programs.

"Research trained Ph.D.s are inadequately prepared to meet the challenges and responsibilities of state extension specialists." If Brown is right in this statement, this may have a profound implication for the long-run survival of extension education. Extension may need a national training center to teach state specialists how to be state extension specialists. A small amount of "how to teach" could greatly enhance a young extension specialist's extension program. Some form of a national "Winter School" for state specialists could greatly expand extension's human capital.

Diesslin presented a good overview and considerable insight into the FACTS system. The integration of research into extension software greatly enhances the value of computerized decision aids in extension. Purdue's pioneering effort in this area with its MIRACLE system is extremely significant. Research can and must play a major role in the subject matter content and the associated data bases used in extension's computer models. Without it, our computer delivery systems will fail due to information voids.

Extension has a proud history and has played a major role in American agriculture. We are not, however, without our problems. Hildreth and Armbruster, Brown, and Diesslin have drawn our attention to some strengths and weaknesses of extension. By capitalizing on these strengths and working on the weaknesses, extension can continue to play a major role in agriculture.

Harlan Hughes is AGNET Coordinator and an associate professor, Division of Agricultural Economics, University of Wyoming.

On the Power of Macroeconomic Linkages to Explain Events in U.S. Agriculture

Bruce Gardner

The significance for agriculture of macroeconomic events in the 1980s depends upon what elements in the macroeconomy are most strongly linked to agriculture and how these linkages function. It is idle to say, for example, that inflation poses particularly serious problems for agriculture in the 1980s unless we have evidence that inflation generally causes particularly serious problems for agriculture. This paper concentrates on the past literature and current state of evidence on such questions. The final section considers the possibility of scientifically defensible forecasts for the 1980s. It is short.

Theories of "Sectoral Macroeconomics"

Many economists have emphasized the importance of not treating the farm sector as a partial-equilibrium island, and a few have worked diligently at building the needed analytical and empirical bridges. Notable early examples are Kirk, Schultz, Hathaway, and Firch (1964), all of whom linked agricultural instability to business cycles. The period in which Hathaway and Firch wrote was the high-water mark of the "Keynesian" approach to these issues, which emphasized the uses of macroeconomic policy. Following the recent disintegration of the theory of macroeconomic policy, the theme of macroeconomic instability returns. Some prominent hypotheses are: "Instability in farm income has its origins chiefly in business fluctuations" (Schultz, p. 214). "Agricultural prices and income are not extremely sensitive to [macroeconomic] changes" (Lamm, p. 30). "National inflation exerts a real price effect on the farming industry, reducing the parity ratio" (Tweeten and Griffen, p. 10). There is also the denial of the preceding hypothesis (Schluter and Lee); "inflation dampens productivity growth" (Ruttan, p. 896); and the denial of this hypothesis (Johnson). Schuh (1974) saw the exchange rate as an important determinant of real farm prices. Other hypotheses are that "inflation has contributed to a greater degree of inequality among regions and types of farms" (Robinson, p. 904); "the major long-run effect of inflation is perhaps in the way it affects the prices of fixed assets, primarily land for agricultural purposes" (Penn, p. 892); and that inflation "leads farmers to expand their operations more aggressively" (Schertz and Harrington, p. 64).

The derivation of these hypotheses tends to be theoretically ad hoc, as well it might be since standard macroeconomic theory provides little guidance. The empirical evidence adduced has been sparse and contradictory. There is a general hypothesis that instability in aggregate demand causes instability in relative commodity prices, which is supported by recent research (Vining and Elwertowski, Parks). Consequently, we expect real farm prices and incomes to be more variable when the general price level is more variable, as Firch (1977) indeed found. But the effect of macroeconomic disturbances on the level of real farm prices and incomes remains an open question.

Systematic connections between macroeconomic aggregates and sectoral variables may occur along the following lines: if an unanticipated exogenous event occurs (such as accelerated growth in the money supply), there will be a sequence of price and interest rate adjustments throughout the economy that will affect some sectors earlier than others. If these transmission mechanisms are stable—perhaps functions of capital intensities, industry structure, prevalence of long-term con-

Bruce Gardner is a professor, Department of Agricultural and Resource Economics, University of Maryland.

tracts, or other specific characteristics of the industry—then we expect a particular time path of adjustment in agriculture (and each other sector) in response to such shocks. Thus, farm prices will rise faster than nonfarm prices if the transmission mechanism works in certain ways, e.g., if prices in competitive auction markets adjust more quickly than prices in imperfectly competitive markets.

The roles of long-term contracts and differential changes in anticipations can be incorporated in a general discussion of price elasticity of supply and income elasticity of demand as determinants of macroeconomic influence on a particular sector. The ideas go back at least to Cairnes, who associated price transmission with sector-specific demand impacts and short- and long-run supply elasticities (see Bordo). The predictions of this approach are not as straightforward as they may appear at first glance. For example, one might expect farm prices to increase rapidly in response to an unanticipated increase in aggregate demand because intended crop output is costly to change during the period when crops are growing. On the other hand, shocks can be buffered by changes in stocks or international trade. Moreover, many nonagricultural goods are subject to relatively fixed capacity constraints in the short run, and long-term contracts with prespecified nominal prices appear more prevalent in nonagricultural industries. In short, while we expect sector-specific price effects of some kind, it is a matter of empirical investigation to discover what these effects are.

The null hypothesis in this situation does not incorporate a "wrong" sign for any variable (hence two-tailed statistical tests are appropriate). Alternative null hypotheses are that all sectors respond to macroeconomic shocks at about the same rate; or that the differential responses are random, so that a sector that gains in one inflationary episode is just as likely to lose in the next. Unfortunately, independent inflationary episodes are scarce. While the years 1960–76, for example, contain sixty-eight quarters, they may contain only four or five underlying inflationary shocks, and hence give only a few degrees of freedom in studying sectoral redistribution. This is probably why Tweeten and Griffen can obtain "statistically significant" results that the parity ratio falls under inflation, while Schluter and Lee find the opposite results for a more recent (but shorter) time period.

While the fewness of inflationary episodes suggests the use of a lengthy time series of data, this increases the likelihood that structural change has occurred during the period being considered. So we are presented with the following dilemma in empirical work: a short time series is unlikely to provide generalizable results about macroeconomic effects because there will be too few significant macroeconomic events; but in a long period the structure of agriculture may have changed so much that there are no generalizable results.

Some macroeconomic hypotheses involve factor-market linkages, e.g., there is "an increasingly close link between the rural sector and the general economy by means of factor markets" (Gardner, p. 22). One of the few sectoral models to emphasize these linkages is Lamm. The ideas derive from Walrasian general equilibrium rather than Keynesian models, involving sectoral linkages more closely related to standard supply and demand models. In particular, we expect labor returns in the farm sector to be strongly influenced by nonfarm labor returns, and the rate of return to investment in agriculture to be closely linked to rates of return in the general economy.

Data on Agriculture in Recessions and Inflations

Table 1 shows in calendar-year aggregates what happened in U.S. agriculture during recessionary and inflationary periods. A year is defined as recessionary if real GNP fell from the preceding year (except 1947 and 1949). To define an inflationary period, I considered two criteria. The first is the set of years when the year-over-year CPI increased 4% or more. The second is the set of years in which the actual rate of inflation exceeded the anticipated rate of inflation, i.e., when unanticipated inflation occurred. This criterion derives from the "rational expectations" view that people adapt to anticipations such that only unanticipated changes in the inflation rate have real effects. For example, because of experience in the early 1970s, an inflation rate of perhaps 6% was generally anticipated for 1977, so that interest rates, rental rates on capital, and so forth reflected this expectation; and had the inflation rate turned out to be 6%, all prices would have adjusted without dislocations of real economic activity. What makes

Table 1. Economic Indicators of the Farm Sector in Recession and Inflation

Year	Real Farm Prices[a]	Real Net Farm Income	Real GNP	Real Farm Land Price	Real Farm Wage Rate	Real Nonfarm Wage Rate
	(% annual change)					
Regressions[b]						
1974–75	+14.4	−29.1	−1.8	+7.6	+1.1	−1.3
1970	−4.0	−7.0	−1.4	−2.3	+1.5	−0.9
1958	+3.6	+11.7	−1.4	+3.6	+2.9	+1.9
1954	−3.6	−5.2	−0.5	−4.3	−2.2	+1.8
1949	−14.2	−36.9	+0.6	+3.2	−1.0	+4.6
1938	−24.0	−35.1	−3.9	+1.9	+1.9	+1.9
1930–32	−21.3	−35.0	−12.3	−2.0	−13.8	−0.6
1927	−1.7	−2.2	−1.8	−1.1	+1.9	+1.9
1924	−0.2	−4.6	−0.2	−3.0	+4.6	+3.5
1921	−30.3	−46.1	−9.3	+2.3	−1.1	+3.4
1914	−1.3	+9.4	−3.9	−1.3	−1.3	−1.3
Average	−11.3	−24.2	−4.9	+0.6	−5.2	+0.8
Inflation years[b]	+2.8	+0.9	+3.5	+1.3	+3.4	+2.2
Unanticipated inflation[b]	+3.1	+4.0	+3.4	+1.1	+2.4	+2.4
All years, 1910–79	−1.1	−2.6	+2.9	+0.8	+1.3	+2.1

[a] "Real" means deflated by the consumer price index. Sources of data: U.S. Department of Agriculture, U.S. Department of Commerce, and U.S. Council of Economic Advisers.
[b] For definition of "recession," "inflation years," and "unanticipated inflation," see text.

1977 an inflationary year is that the inflation rate accelerated to 9%.

To estimate anticipated inflation, I fit an ARIMA model to natural logs of the CPI. The anticipated rate of inflation is the forecasted value for each year from the differenced CPI time series. The ARIMA (1,1,1) model over the 1910–79 period is

$$I_t = \underset{(0.158)}{0.314}\, I_{t-1} - \underset{(0.138)}{0.554}\, e_{t-1} + e_t,$$

where I_t (= change in log CPI) is the rate of inflation in year t, and e_t is the forecast error. The numbers in parentheses are standard errors of the coefficients. The forecast for I_t is made as soon as I_{t-1} and e_{t-1} are observed. This specification fits better than a simple first-order autoregressive or moving-average process (i.e., adaptive expectations), or a random walk as used in Parks (p. 90). But higher-order AR or MA lags do not significantly reduce forecast errors, and the autocorrelations of the residuals from the fitted model are not significant.

Given the ARIMA forecast as the anticipated rate of inflation, years of unanticipated inflation are defined as those in which the actual rate exceeds the predicted rate by one standard error (3%) and in which the rate of inflation was positive (to exclude decelerations of deflation in 1922 and 1934). These years are 1916–20, 1941–42, 1946–47, 1951, 1971, 1973–74, 1977–79. The years in which the CPI rose more than 4.0% are the same except that 1943, 1948, 1969–70, and 1975–76 are added. Note that 1970, 1974, and 1975 are years of simultaneous recession and inflation under one or both criteria of inflation. And of course there are many years, forty-six out of seventy in the 1910–79 period (although only one in the 1970s), in which neither inflation nor recession is observed.

The performance of agriculture during recessions is variable, as the table 1 data indicate, but on average the farm sector fares poorly during these episodes. Farm income tends to fall substantially more sharply than overall GNP, as do farm prices relative to the general price level and farm wage rates relative to nonfarm wage rates. Thus, it appears that agriculture has an even greater stake than other sectors in avoiding recessions, although the differential effects are less pronounced since 1950. (The substantial farm income decline in 1974 is misleading, being measured relative to the extraordinary year of 1973. 1974–75 was still well above 1970–72 in real farm income.)

The effects of inflation are roughly similar under both criteria for inflation. For the nonfarm variables and for farm wage rates and land prices, the inflationary periods do not differ appreciably from the seventy-year mean rates of growth. However, real farm product

prices and real farm income grow faster in the inflationary years, particularly in years of unanticipated inflation.

Econometrics of Macroeconomic Linkages

Two serious deficiencies of the table 1 data are that they provide no indication of the statistical significance of the observed differences, and they leave out everything else that happened during recessions and inflation besides these macroeconomic events. In an attempt to remedy these deficiencies, this section develops regression models for these data. Table 2 shows results for real farm prices. Regression 1 indicates effects of about the same magnitude as the averages reported in table 1, but the effect of inflation is not statistically significant. This is the same result found by Grennes and Lapp.

Regressions 2–7 include other variables that may be influencing farm prices. The variables added in regressions 2 and 3 pertain to long-term forces underlying U.S. farm prices, while regressions 4 and 5 add variables on output changes and exports, which may be more important in determining short-term price fluctuations. Output changes clearly influence price changes but also are clearly endogenous variables. However, it seems likely that output changes contemporaneous with farm price changes are caused primarily by weather, or similarly exogenous forces, rather than being production responses to contemporaneous price changes. Lagged output is included along with current output because the calendar-year basis of the price index results in two crop years being relevant to the observed price change.

Exports also involve obvious problems of mutual determination with prices, but analysis of the time series did not detect causality going from prices to exports. For recent years, it is possible to include an additional export-related variable, the exchange rate of the dol-

[a] All continuous variables are percentage changes, so coefficients are elasticities. Definitions and sources of variables: recession and inflation dummies defined in text; productivity is USDA's index of total factor productivity, smoothed using a fitted fifth-degree polynomial (no trend in 1910s, gradually rising in 1920s and 1930s, accelerating in 1950s and 1960s, decelerating in 1960s and 1970s); nonfarm wage is Department of Commerce hourly wage rate in U.S. manufacturing; government program dummy is 0 through 1932 and 1 thereafter; exchange rate is the Federal Reserve Board's trade-weighted dollar; exports are U.S. Department of Commerce estimates of the value of agricultural products exported; output is USDA agricultural output index, 1967 = 100. All dollar variables except the exchange rate are deflated by the CPI.

[b] Regressions containing the exchange rate cover 1956–78 only.

[c] "*t*"-statistics.

lar for foreign currencies. An interesting literature has grown up around Schuh's hypothesis that an overvalued dollar was a prime cause of agriculture's problems in the pre-1972 period. Of the variables that have been suggested for use in testing this hypothesis, the most attractive is a trade-weighted dollar, an index of exchange rates of major currencies weighted by the share of trade accounted for by each country. Such a variable is included in regression 5. Since it is only available after 1956, this regression covers a much shorter time period than regressions 1–4.

The results are quite different for the shorter time period. Output, productivity, and nonfarm wages all become insignificant.[1] The most significant variable is the exchange rate, whose coefficient indicates that a 1% fall in the value of the dollar generates a 0.4% increase in real farm prices. Most important for the present discussion, there is no longer any significant effect of being in either a recession or an inflationary period. This bears out what the table 1 data indicate for recessions—that they no longer are as important to the farm sector as they once were. This is consistent with the findings of Lamm. Regressions 6 and 7 include real GNP and the CPI as continuous variables instead of dummies for particular episodes. The results are basically similar, but the t-ratios and R^2 generally improve.

Table 3 contains regressions explaining real farm income, wage rates, land prices, and prices paid by farmers. The recession coefficients tell the same story as the raw data of table 1–the significant effects are to reduce the real farm wage rate by about 5% and real farm income 23%–24%. The effects of inflation are insignificant on all the real variables (also true for years of unanticipated inflation, although to save space these regression results are not shown). This conflicts with Tweeten, who found inflation to increase real prices paid by farmers.

Regressions 9 and 13 show results for the

[1] The F value for the short-period residuals is 0.76, indicating insignificance for the regression as a whole. Seemingly much "better" results occur with regressions on levels rather than changes. Regressions 5-6 specified in terms of levels yield much higher R^2. But the Durbin-Watson statistics are less than the R^2, indicating that "significance" of results and apparent good fits may be spurious. (See Granger and Newbold, pp. 202–14.)

[a] Same as in table 2.
[b] Net farm income is the USDA's estimated total net income from farming. Prices paid is the USDA index for production items. The farm wage rate is the USDA index, as is the farm real estate price. All are deflated by the CPI.
[c] "t"-statistics.

1956–78 period. The recession effects are weaker in this period. Note that the exchange-rate variable is highly significant, as it was in the output-price regression. However, in the land-price regression, the exchange rate has a positive sign, which means that depreciation of the dollar is associated with lower land prices, an unexpected result. Note also that the land price is the only dependent variable in the table 3 regressions for which the government-program dummy has a significantly positive effect. The hypotheses that inflation increases the real prices of fixed assets and the rate of growth of farm size (Penn; Schertz and Harrington) lack evidential support. While the raw data of table 1 show real estate prices rising 1% to 2% faster in inflationary years, regressions 12 and 13 show no effects of inflation on real land prices.

Alternative econometric specifications to those of this paper include the following: one could model less aggregated commodities, as in Chen; one could imbed the farm sector in a fuller model of the rest of the economy, as in Cromarty, Fox, Shei and Thompson, or Lamm; or the specification of the foreign market influences on the U.S. farm sector could be more complete, as in Grennes and Lapp. A detailed model of the agricultural sector, fully integrated with a model of the general economy, would permit study of macroeconomic effects on agriculture simultaneously with the effects of agriculture on the rest of the economy. An assumption of my regressions is that a fully specified model is not necessary to identify macroeconomic effects upon agriculture. Because agriculture is a small part of the general economy, the dominance of causality from the general economy to agriculture seems plausible, but fuller models are necessary to test the assumption.

A few small-scale simultaneous models have been developed, notably Lamm, Shei and Thompson, and Chambers and Just. I have found the results in these papers suggestive but inconclusive in establishing the nature of sectoral linkages. Chambers and Just find that "a sustained 10 percent reduction in domestic credit would eventually evoke more than a 17 percent change in the level of wheat price, a 7 percent change in corn price and an 11 percent change in soybean price" (p. 17). This is a quite implausible result, and it is not clear that the differences are statistically significant. Shei and Thompson conclude that Soviet grain purchases had a substantial effect on the general price level in 1973, while over a longer time period Lamm concludes that "changes in the rest of the economy have large effects on agriculture, while the converse is not ordinarily the case" (p. 32). Overall, the evidence adduced in these papers is far from settling the issues.

Firch (1977) considers subperiods of data that are suggestive of structural change over time in macroeconomic influences on agriculture. He finds, for example, that inflation was a more prominent agent of instability in 1920–39 than in 1946–75. The weakness of his approach is the lack of tests of significance for time-varying effects.

Evidence on instability is obtainable by a modification of regression 7 above in which the log changes of price, the inflation rate, and other variables are squared. This transformation generates a component of the log variance of price and other variables, so that a zero coefficient on an independent variable means that it contributes negligibly to variation in the dependent variable. A significantly positive coefficient on variability confirms the hypothesis of Parks that instability in the general price level generates instability in real sectoral variables. For the 1910–78 period, regression 7 as transformed yields a statistically significant effect of price-level variability increasing the variability of real farm prices. The shorter period 1956–78 as respecified shows a smaller instability effect, but a null hypothesis of no structural change in the regression coefficient over time cannot be rejected. The overall result is to confirm for agriculture the Parks and Vining-Elwertowski results that macroeconomic instability has real sectoral effects. But it remains the case that there is no predictable direction in which real farm prices are affected by general inflation.

Implications for the 1980s

In 1969, Egbert derived the following policy implication from his sectoral model: "Some form of production controls will continue to be needed in agriculture to maintain prices and incomes, at least for the next decade" (p. 31). The most convincing explanations of what happened to make this and similar forecasts look ridiculous in the 1970s are macroeconomic linkages. Are we now equipped to speak with any better authority about the 1980s? It would be rash to suppose so. But

there may be better prospects for preinterpretation of the 1980s, that is, projection of the kinds of influences that it will be most important to watch for, and forecasts conditional on salient contingent events.

In the research to date I see three main channels of influence from the rest of the economy to agriculture. They are (*a*) "Walrasian" influences—the forces associated with the attainment of neoclassical general equilibrium between sectors, most notably equalization of rates of return in factor markets; (*b*) "Marshallian" influences—the effects of standard shifters of supply and demand curves, such as consumers' incomes or population; and (*c*) "Keynesian" influences—a catchall for the nonstandard hypotheses such as those of Schultz, Firch, and Schuh.

The Walrasian view of agriculture's connection with the rest of the economy has not been as prominent in the recent literature as the Keynesian hypotheses. Nonetheless, this approach holds promise for preinterpretion of the 1980s. Schuh (1962) and many successor studies on farm labor indicate that the most important determinant of farm wage rates is nonfarm wage rates. More recent work, notably Melichar, Hughes, and Feldstein, is establishing the groundwork for similar conclusions in the capital markets. From this point of view, the most important determinants of the trend of farm factor returns in the 1980s will be factor returns in the general economy.

The Marshallian linkages dominate the early sectoral models of Cromarty, Fox, and Egbert, although they were developed in conjunction with Keynesian macromodels. The inflation rate, for example, does not enter into the determination of relative farm commodity prices, nor does the exchange rate or other nonstandard influences. This continues to be the case for large farm-sector models such as Chen's. Thus, preinterpretion of the 1980s using such models will not involve the issues which have been emphasized in this paper, except insofar as real GNP influences demand functions.

The main "Keynesian" variables that appear to possess explanatory power in the historical data are recessions and the exchange rate. But recessions are not important after 1950 (and GNP is not that nonstandard anyway). Moreover, on further consideration it is dubious whether one can expect future fluctuations in the foreign value of the dollar to play a major role in the real well-being of the farm sector in the 1980s. The reason is that the effect, for example, of the exchange rate in regressions 5, 6, and 9, above, results from the switch from a fixed to a flexible exchange-rate system, which took place in two steps in 1971 and 1973. (This is revealed by the fact that an exchange-regime dummy that captures only the fixed versus floating contrast picks up virtually the whole exchange-rate effect, while the exchange rate itself, in the presence of the structural-shift dummy, becomes insignificant.) So one cannot use the exchange-rate coefficient to forecast effects of future exchange rate fluctuations under the floating-rate regime. There may well be real exchange-rate effects, but these will turn on deviations from purchasing-power parity in exchange rates, a topic on which future research should be given high priority, but on which there is not yet enough knowledge to base forecasts.

The "Keynesian" preinterpretations of the 1980s that I have to offer are thus negative: even if I knew the future course of U.S. business cycles, inflation, and foreign value of the dollar, I could not predict any particular consequences for agriculture (compared to other sectors). Of course, to predict nominal prices, we need to forecast the general price level, and for this we need a macromodel. But there is no evidence that the best macromodel for the purpose has anything agricultural in it. Thus, there is no reason to believe that agricultural economists can forecast better by expressing their models in nominal values (as most of the papers cited in the list of references do) and then incorporating determinants of the overall price level such as the money supply on the right-hand side. With further research this situation may change, but for forecasting the 1980s at our present state of knowledge, I believe it preferable to use the macroeconomists' models for the economy-wide variables and sectoral models with deflated prices for agricultural variables. In short, the classical dichotomy between real and nominal values prevails in practical forecasting of annual data.

Agricultural Land: Adequacy of Acres, Concepts, and Information

Michael F. Brewer and Robert F. Boxley

The authors were implicated to varying degree in the recent National Agricultural Lands Study (NALS). In addressing our assigned topic of the "adequacy" of agricultural land for the 1980s and beyond, we draw on the NALS experience.

NALS was a multiagency federal study under the joint sponsorship of the U.S. Department of Agriculture (USDA) and the President's Council on Environmental Quality. NALS was charged with determining "the nature, extent, rate and causes of reductions in the land base of U.S. agriculture," evaluating its "economic, social and environmental consequences," and recommending "administrative and legislative actions, if necessary, to reduce losses suffered by the nation as a result." As with previous efforts of this type, the root question prompting the investigation was whether the future consequences of current trends in land use warrant policy intervention in the processes that now allocate the resource.

This heavily publicized and widely reported exercise yielded multiple, and at times inconsistent, products. These include findings from staff research, various pamphlets and "Interim Reports," and a separately drafted *Final Report* that was filed in the closing hours of the last administration. The latter contained new forecasts of future land requirements based on last-minute revisions of previous projections by USDA.

The study furnished graphic examples of difficulties researchers can encounter in exploring subjects that many perceive as articles of faith, and that are suffused with vested interests and foregone conclusions (Cook 1980, 1981). Regardless of what the NALS *Final Report* advanced as findings and recommendations, history suggests they will not lay the issue to rest. As with debates on the need to control population or the limits to growth, agricultural land adequacy seems to have a cyclical claim on the public's imagination, anxiety, and credulity (Luten). We are not sanguine that the NALS will break that cycle. Efforts to determine the "nature, rate, extent and causes of reductions in the land base," led NALS into a morass of inconsistent and conflicting numbers that left issues possibly more confused than previously. Instead of a broad "economic, environmental, and social evaluation" of the consequences of agricultural land conversion, the *Final Report* based the substantive case for a federal role in agricultural land preservation almost solely on the question of when the nation "runs out" of suitable agricultural land.

This paper undertakes to (*a*) describe the current agricultural land situation, focusing on definitional and measurement problems; (*b*) discuss the adequacy of agricultural lands for the 1980s and beyond, where "adequacy" is defined by the standard criterion; and (*c*) explore whether other criteria might be preferred.

The Definitional Morass

An initial task for the NALS staff was to develop a definition of "agricultural land" consistent with its mandate. The mandate was seen to arise out of the nationwide concern about the "loss" of private farmland and from federal, state and local efforts to stop it. The mandate was further perceived as relating almost entirely to the private sector since most farmland is privately owned, and most land use conversions are the result of market decisions. In the final round, the definitions were also influenced by data availability.

The authors are, respectively, former research director and research economist with the National Agricultural Lands Study.

Suggestions and critical review of an earlier draft by William D. Anderson are gratefully acknowledged by the authors.

NALS defined agricultural lands as "lands currently used to produce agricultural commodities including forest products, or lands that have the potential for such production. These lands have a favorable combination of soil quality, growing season, moisture supply, size, and accessibility. This definition includes about 590 million acres of land that have no potential for cultivated crop use but are now in agricultural uses, including range, pasture, or forestland" (*Final Report,* p. 21). The measure of agricultural land that NALS adopted was expansive. It includes all nonfederal rural land not actually in "nonagricultural" uses—e.g., rural transportation rights-of-way, water impoundments, or other nonfarm uses. Though chosen in good faith, it is clear in retrospect that both the definition and measure are flawed.

Figure 1 presents the taxonomic breakdown used by NALS. It is based on definitions and statistics from the Soil Conservation Service's, 1977 *National Resource Inventory* (NRI).[1] The first major division in figure 1 is between federal and nonfederal land. This division was seen as consistent with the NALS focus on privately owned lands, since only a minute amount of federal lands is used for crop production (*Final Report,* p. 27).

The next division, "rural" and "urban," is straightforward enough, except for continuing problems of defining and measuring urban lands. Rural land (1,443 million acres), less lands in rural transportation, other nonfarm, and water uses, yields the quantitative NALS measure of agricultural lands (1,361 million acres).

This measure has at least two technical deficiencies as well as a major connotative problem. First, if agricultural commodities are defined to include forestry or grazing output, then the land base is undercounted by half a billion acres of federal lands that contribute importantly to both timber and livestock pro-

[1] In addition to the definitional issue, there are also concerns that quantitative differences among NRI and other source statistics on land use or land use change. There are discussed in McGill, Hidlebaugh, Yovino; Boxley; Brewer and Boxley.

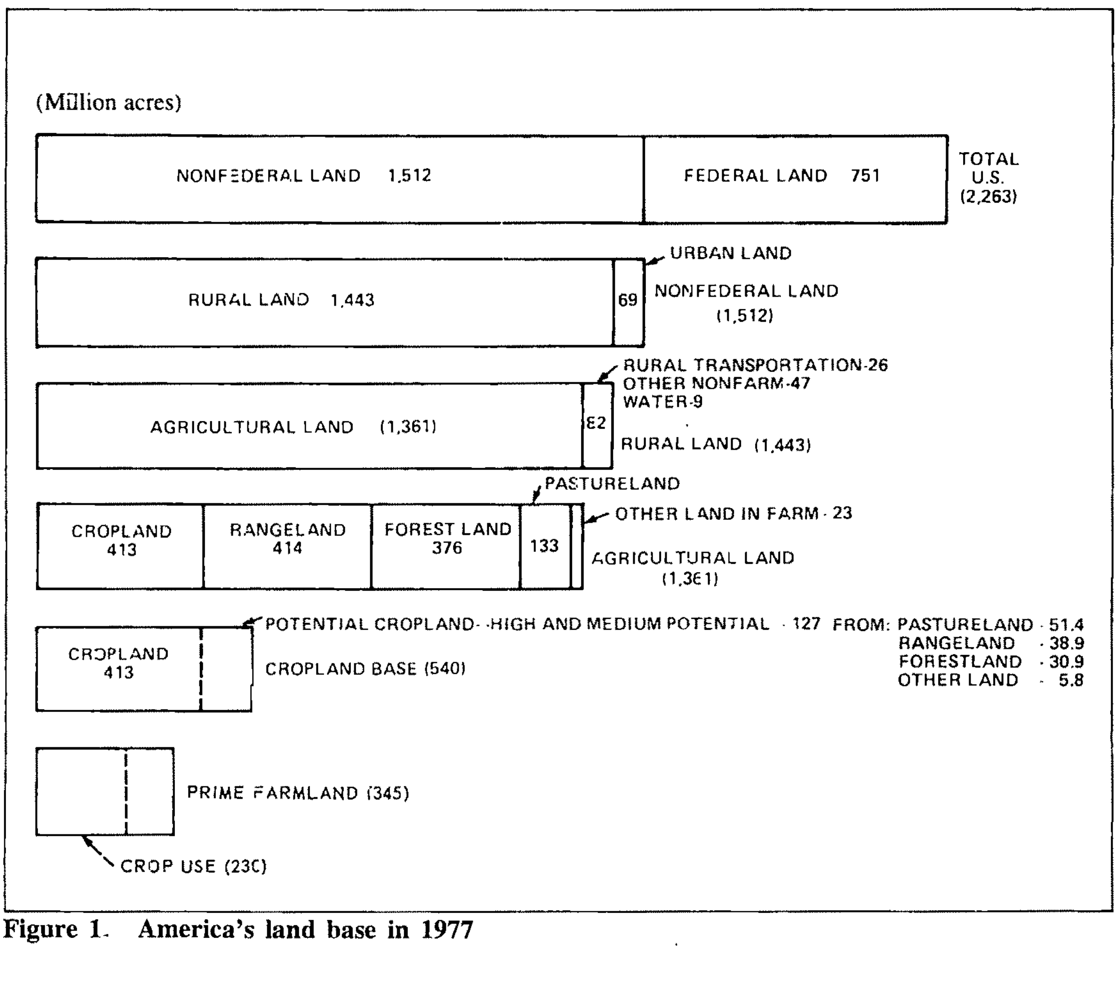

Figure 1. America's land base in 1977

duction.[2] Second, the definition is in part a tautology. Agricultural land, as defined, has to have some minimally favorable combination of soil quality, growing season, and moisture supply; otherwise the land would be barren. But sufficient climatic and soil characteristics to support, however tenuously, a range or forest biome does not necessarily signify economic importance (supramarginal productive capacity), as the last part of the definition implicitly recognizes.

The connotative flaw arises from insufficient distinction between "agricultural land," "cropland," and "farmland," inviting their confusion. Though the *Final Report* avoids equating these different categories, few other reports, including several issued by NALS, observe the distinction. Rarely, if ever, is "farmland" defined.[3] The agriculturalist probably equates "farmland" to the 1.05 billion acres the USDA and census count as "land in farms." For others it might as easily connote the 465 million acres of cropland and cropland pasture enumerated by ERS or the 387 million acres of cropland used for crops in 1980. Clearly—and unfortunately—the *Final Report* does not clarify the babel of tongues about agricultural land.

Although not emphasized, NALS also reported on "prime farmland." Its Agricultural Land Data Sheet includes the 345 million acres of prime farmland enumerated in the 1977 NRI, of which 230 million are cropland. This category is simply defined as "the best land for farming." The ambiguity of the prime farmland concept has been well noted (Woods, Smith and Barrows).

Agricultural Land Conversion

All of the above might be dismissed as hair splitting except for the uses made of the numbers. Two recent sources of statistics on land use change were available to NALS—the 1975 *Potential Cropland Study* (PCS) and the 1977 *National Resource Inventory* (USDA). NALS elected to use the PCS as the source of land use change data, primarily because different enumeration procedures were used in the 1977 inventory (Brewer and Boxley). Data from the PCS indicate that for all categories of what NALS defines as agricultural land, about 3 million acres were converted to nonagricultural uses annually between 1967 and 1975. This formulation poses a "bait-and-switch" problem for the unwary. Almost invariably, the press and the pamphleteers report this as farmland conversion. Lauren Soth, for example, writes: "The government's recent National Agricultural Lands Study found that 3 million acres of farmland are lost to urban developments each year."[4] A more lurid version has it: "In the war between the bulldozer and the plow, one million acres of America's prime farm land are urbanized each year. . . . In addition to the prime land loss, we are losing another two million acres of lesser quality, nevertheless productive, agricultural land to nonagricultural conversion each year" ("Where Have the Farm Lands Gone?" p. 8). Another major paper interprets it as: "The Agricultural Department says conversion of actual and potential cropland to nonfarm use is at the rate of three million acres a year . . . *Wall Street Journal*).

Of the 1.4 billion acres of agricultural land defined by NALS, 856 million acres have either low or zero potential for cropland (268 and 588 million acres, respectively). The PCS estimates that about 675,000 acres of cropland were converted to urban-type uses annually between 1967 and 1975. The conversion of rangeland, forest, or other land in farms with high or medium potential for cropland use was not enumerated separately but is estimated to have been perhaps 200,000 acres annually. Thus, the conversion from the 540 million acres "cropland base" of figure 1 was around 875 thousand acres annually between 1967 and 1975. Since it is these 540 million acres against which questions of future adequacy are judged, the "loss" by conversion should be related to this cropland base rather than the essentially meaningless measure of "agricultural land."

A related and important issue partially explored by the NALS research staff questions the appropriateness of past rates of

---

[2] The *Final Report* (p. 27) estimates that about 500 million acres of federally owned land is "agricultural land" (i.e., used for crops, grazing, or forests). It then goes on to ignore this huge quantity of land, saying: "The NALS mandate covers the Nation's entire 1.36 billion acre agricultural land base. . . ." (p. 38).

[3] The following titles provide examples: "Where Have the Farmlands Gone? (NALS pamphlet), "The Protection of Farmland" (a report to the National Agricultural Lands Study from the Regional Science Research Institute), "Disappearing Farmlands" (National Association of Counties Research Foundation) "Land and Food, The Preservation of U.S. Farmland" (American Land Forum).

[4] The author does, however, go on to point out that only 1 million of the 3 million acres are cropland.

change as harbingers of the future (Brewer and Boxley). All the statistics on land conversion were generated in a period that differs substantially from the present; it is unlikely that the pressures for land conversion in the 1980s will remain the same. We anticipate that the 1982 National Resource Inventory will shed light on more recent land use trends.

Potential Cropland

In 1980, the total amount of cropland used for crops (387 million acres) was back at the peak quantity reached in 1949. These are not, of course, identical acres because U.S. agriculture experienced major geographic shifts in the intervening years (Horsfield and Landgren). Nevertheless, if food and fiber demands materialize in the 1980s as projected, we will be moving onto a segment of the supply curve for land for which we have no previous observations.

The only estimates of what the source of new cropland might be are the Soil Conservation Service surveys of 1975 and 1977. The 1977 NRI estimated that the nation had 36 million acres of land with high potential for crop use and 91 million acres with medium potential (fig. 1). The 1975 study found slightly less land with high or medium potential (111 million acres), but the relative proportions of high to medium potential cropland was reversed (Diderickson, Hidlebaugh, Schmude, p. 5). Unfortunately, the price-cost assumptions that went into the construction of these estimates were not well-specified. Building on some initial work by Robert Otte, Fox and Clayton showed that the change in relative proportion of high- to medium-potential cropland for the two years was consistent with the change in the ratio of the index of prices received to the index of prices paid in the years preceding each survey (the ratio was 117 in 1974 and 97 in 1976). Based on these relationships, Fox and Clayton then extrapolated a supply relationship for cropland under five price-cost relationships (p. 74).

These relationships are vague, as Fox and Clayton note, because they are based on neither absolute levels of prices paid or received nor on net farm returns. The point to be made is the paucity of well-founded economic data for estimating future land availability for agricultural production.

Future Land Requirements

Acknowledging the imprecision of measures of supply and uncertainty about flow of agricultural land services, we move on to the demand side of the equation. At the beginning of NALS, several major assessments of future land requirements were underway (notably the program assessments of the Forest Service and the Soil Conservation Service, USDA; the *Global 2000* report; and at Resources for the Future). These assessments were used to prepare baseline projections in an NALS research paper (Boxley). In addition to these projections, the *Final Report* contained year 2000 forecasts of demand growth, crop yields, and planted acreage requirements based on work by O'Brien (p. 52).

These studies defy easy summarization. Suffice to say, the estimates of additional cropland required to meet year 2000 demand projections at constant real prices range from a low of 36 million (Boxley, p. 139) to a high of 113 million acres (*Final Report*, p. 59).

The assessments reviewed reveal the following characteristics:

(*a*) In contrast to projections made in the 1960s and 1970s, recent projections are more expansive in estimating demand growth and more conservative, or at least more hedged, in projecting yield or technology increases. Thus, they are less optimistic, or more "scarcity"-oriented than projections of just a few years earlier. A tendency to weigh the recent past most heavily in projecting the future can be seen clearly. Whether this is a belated, but warranted, adjustment of expectations or an overreaction to the near term remains to be seen.

(*b*) Most of the projections are based on comparative-static, constant-price analysis. The essence of this analytical technique is, first, to calculate the expected future change in commodity demand, given certain assumptions about demand shifters deemed most important (U.S. and world population growth, changes in tastes and preferences, international trade patterns and policies, and, in some models, inflation). Second, the expected growth in supply owing to increased crop yields, productivity, or changing factor combinations of nonland inputs is calculated. Since virtually every future scenario of recent vintage anticipates the rate of demand growth will exceed the rate of yield or productivity increases, land becomes the equilibrating fac-

tor. Thus, the third step of the projection technique is to calculate the change in the land base (net of "losses" to urban or other nonagricultural uses) required to restore equilibrium between the projected quantities demanded and supplied.

This standard methodology has major shortcomings. In a market economy, price is the principal equilibrating mechanism. Only with an infinitely elastic supply of land would the real world track the projection. With a less than infinite elasticity, the process of equilibrium entails movements along the demand and supply curves. As noted above, reliable measures of land supply elasticity are unavailable. It is neither surprising nor inappropriate that predicted land requirements are greeted with distrust.

A further problem with this technique is the burden placed on land as the residual equilibrator and, by implication, as the dominant policy instrument. With respect to the first point, every item in the vectors of demand and supply shifters is subject to uncertainty or vulnerability to change. The comparative-static nature of the model is inadequate for dealing with multiple sources of uncertainty. The power-function nature of possible combinations and permutations of these shifters is inconsistent with the conventional process of constructing scenarios to reflect a range of possible outcomes. To say that the range of possible additional cropland requirements by the year 2000 is between 36 and 113 million acres is unlikely to strike many as a reassuringly precise estimate.

Reliance on land as the equilibrating factor also implies that agricultural land preservation is the most important policy instrument for dealing with questions of adequacy. It clearly is not. The highest estimate of additional cropland likely to be converted to urban use by 2000 is 20 million acres (Boxley, p. 138). A land preservation program that could halve that rate of conversion undoubtedly would be considered highly successful. Yet, the additional output from 10 million acres could alternatively be achieved, for example, with about 0.25% increase in the annual rate of growth of crop yield, as calculated by O'Brien (*Final Report*, p. 59).

If the issue is assurance of adequate productive capacity for the year 2000 and beyond agricultural land preservation programs on aggregate production capacity grounds may be ignoring considerable opportunity costs.

Adequacy of Agricultural Lands for the Future

"Adequate" is an elusive concept. If the question is physical adequacy, then most combinations of numbers (however imprecise) that we have discussed in the previous two sections suggest that we have a physically adequate stock of agricultural lands. But the issue is economic, not physical.

An economically adequate supply may be taken to mean sufficient to meet commodity demands without imposing significant increases on the costs of their production. If this criterion is employed, the question of adequacy of agricultural lands for the future has important normative dimensions: (*a*) The cost criterion implies normative "correctness" of current or traditional production costs. (*b*) Demand growth is normatively unconstrained; supply must rise to satisfy it. (*c*) The choice of a time horizon involves normative as well as technical choices. Failure to deal with these normative matters relegates moral questions to the status of technical issues, increasing the likelihood of conflict over questions of agricultural land adequacy.

Aside from the inevitability of normativism in any discussion of "adequacy," we are impressed by the continuing reoccurrence of the issue.[5] Since the end of World War II, the question of natural resource adequacy has been repeatedly addressed (Lansburg, Fischman, Fisher; Smith). Past experience has consistently been to overestimate demand growth and underestimate supply responses (Heady, p. 4).

Despite the post-World War II record of agricultural surplus and the persistent wrongness of some thirty years of accumulated forecasting experience, the adequacy issue continues to reoccur. Why?[6] And why have the

[5] The question of adequacy of agricultural land in the United States is, of course, only a part of the larger limits-to-growth debate. As Luten notes, the question of limits of growth and optimism and pessimism regarding the human prospect has been debated, without consensus, for a good two hundred years (Luten,

commissions, studies, and conferences failed to lay the issues to rest for more than a short period? Luten, in an interesting article, proposes that the source of the conflict lies in differences between social and natural scientific faiths that cause the former to be eternal optimists and the latter to be pessimists. Luten argues that the optimists believe in their forecasts and wish them to come true and assume that all forecasters, including pessimists, believe and wish similarly. The pessimistic forecaster, however, has the opposite intent: to cause a public to become concerned and to persuade it to change its conduct so as to avoid a bleak future. Differences evident among NALS staff, and in the perspective of the two major sponsoring organizations of the study, would appear to support Luten's hypothesis.

In addition to conflicts in scientific faiths, the National Agricultural Lands Study was subject to another failing: bias toward the national accounting stance and quantifiable objective functions. This bias, common to arguments pressing the case for agricultural land preservation, often leads to oversimplification of complex, multidimensional issues.

In a recent paper Hite and Dillman speak on this issue. They propose that ideology, not economics, is at the root of the agricultural lands protection movement, and "the rigorous quantitative analysis which is the dominant methodological approach of contemporary agricultural economics does not lend itself readily to dealing with questions of values, traditions, and national character" (pp. 3–4).

They continue, observing that "The agricultural land protection issue is not of a single piece of cloth: some of the best, and most universally felt, reasons for protection have little to do with food prices and production efficiency; attempts at rational analysis are confounded by differences in accounting stance (local, regional, national, and world); and some of the arguments having the greatest emotional appeal are based upon extremely weak premises."

of economists to tackle the issue using the same economic model as before but with conviction that this time it will be done "right." Beyond this, however, is the observation that the issue tends to wax following wars, natural disasters or, as in the last case, economic disruptions—which suggests a tendency to overreact or to react with extreme pessimism to bad news. In the case of the OPEC oil embargo of the early 1970s, the dire predictions of a return to preindustrial agriculture clearly did not materialize and the actual adjustments within the agricultural sector have been more moderate than many predicted (Heady).

In addition to national or global concerns about adequate food supplies, Hite and Dillman enumerate six reasons for land retention programs frequently put forward at the local level.[7] Three of these reasons (local self-sufficiency, production dispersion, and preservation of specialized agriculture) require national accounting stance for validity. The standard economic model, however, cannot address these issues and seldom provides support for local planners who would argue them.

Are There Better Procedures?

We do not have a comprehensive procedure for bridging the gap between the social and biological science perspectives as identified by Luten or for addressing the ideological issues raised by Hite and Dillman. In reflecting on the National Agricultural Lands Study, however, we offer three proposals we think could at least advance rational debate in the next iteration, which is sure to come.

Assess Carefully the Irreversibility of Land Use Change

In 1964, Ciriacy-Wantrup wrote about the "problem of irreversibility" in relation to projections of future social needs. He proposed a land-use strategy based on a "safe minimum standard" of present performance specified in such a way that maximum possible future losses are avoided (p. 257). Wantrup likened his proposal to an insurance policy against serious losses that resist quantitative measurement. Rather than maximizing some quantifiable net gain, the objective is to choose premium payments and benefits in such a way that maximum possible losses are minimized. Two dimensions of Wantrup's formulation are pertinent: (*a*) the existence of an irreversibility that makes conversion a present issue for land policy, and (*b*) the balance of program costs and benefits.

Without disputing its existence, we feel the irreversibility of land conversion has been accepted too uncritically. The common practice

[7] They are: (*a*) protection of agriculture as an important local industry; (*b*) maintain local food supplies or self-sufficiency; (*c*) provide dispersion of food production to prevent national food shortages; (*d*) preserve specialized soils and climatic zones; (*e*) provide open space, recreation, wildlife habitat, air and water recharge capacity, and aesthetics; and (*f*) promote orderly growth of urban areas.

has been to consider all conversions of land to nonagricultural uses as irreversible, and, by implication, to equate "irreversible" with "irreplaceable."[8]

"Irreversibility" has both physical and economic dimensions. Where true physical irreversibility threatens, then the relevant issue would appear to be "replaceability." Although the existence of unique agricultural microclimes are asserted to exist (tart cherry orchards on Grand Traverse Bay, Michigan, artichokes in California) these would appear to be sufficiently rare and localized to warrant individual treatment under a regional or state accounting stance.

Economic reversibility rightfully involves changes in land use at some future time. This requires a complete economic accounting of the discounted flow of income during the intervening years of the converted use as well as the discounted cost of future reconversion. If the issue is seen as a loss of "critical mass" or "agricultural infrastructure," an economic accounting is obligated to consider and weigh the cost of prospective future obsolescence of the present infrastructure against the cost (and efficiency) of building a new infrastructure when it becomes needed.

It may be that careful examination might warrant the conclusion that for all practical purposes the loss of any land to U.S. agriculture is irreversible, as the NALS *Final Report* asserts. The point is that cropland irreversibility is a quantifiable concept that does not have to rest on assertion. One irony of the land preservation drive is that society, in seeking to prevent land conversion by removing certain rights of ownership, may in fact create institutional or legal barriers that will prove truly irreversible, even into perpetuity.

Gauge the Opportunity Costs of Agricultural Land Preservation

Another aspect of Wantrup's "safe minimum standard" strategy is the weighing of future benefit and cost streams. He considered California irrigated agriculture and identified as "insurance premium" the higher construction costs necessitated if urban-industrial development is diverted from the alluvial plains to the benches, foothills, or otherwise inferior locations. Wantrup concludes: "There is, however, some evidence that, in balance, the costs are not too high and are likely to decrease in the future" (p. 259).

Seventeen years later Hite and Dillman returned to the same theme in another area. Asserting that "our efforts as agricultural economists should be focused not so much on attempts to estimate the benefits to such land preservation as on attempts to estimate its costs" (p. 17), they cite a study by Cousins of the cost of resorting to second-best industrial sites in the Greenville-Spartanburg (S.C.) SMSA. Their comments are worth quoting directly:

> To our knowledge, however, his are the only numbers we have of what the opportunity costs of preserving prime agricultural lands might be, and if they are at all indicative of such costs, they suggest to us that the price tag on protecting prime lands will not be low. Indeed, the agricultural use-value, estimated by discounting present net farm income, in perpetuity, of all the prime lands in Greenville County now occupied by industrial plants is only about 8 percent of the minimum added site-preparation costs that would have been forced upon the industries if they had been required to resort to non-prime sites. Before the nation or any locality embarks upon an extensive agricultural lands preservation program, agricultural economists would seem to have an obligation to determine what the opportunity costs are likely to be and make certain the decision makers can gauge just how much prime land they can afford to protect. (Hite and Dillman, p. 18–19)

Recognize Limitations of Statistical Measures and the Ability to Track Changes

In Luten's discussion of the Malthusean corollary, he observes that under conditions of compounded growth, it makes little difference how accurate the estimates of resource magnitude are; scarcity is rarely remote and it comes abruptly (p. 139). He makes the point by retelling the riddle of the lily pond. The pond's open water represents remaining natural resources. Assume exponential growth (so that the water lilies, if unchecked, will cover the pond in thirty days) and that one can estimate the magnitude of open water only to within 10 percent (a generous estimate, Luten believes, of attainable precision for measuring natural resource stocks). For 25 days, open water will not diminish within our ability to measure it with certainty; its value remains at 100 percent. Only on the 26th day does growth

[8] For example, the executive summary of the NALS *Final Report* says: "The United States has been converting agricultural land to nonagricultural uses at the rate of about three million acres per year. . . . For practical purposes, the loss of this resource to U.S. agriculture is irreversible."

approach measurement error (93.75% remaining open water). On day 27, 87.5% remains; on day 28, 75%. Clearly something is happening! On day 29, perhaps it becomes clear that there is a need to deal with the growth, but there is no reason to panic; after all the pond still has half of all the open water it ever had (p. 147).

In a less catastrophic sense, we feel the parable may have applications to the question of agricultural lands adequacy. Citizens who observe what is happening to rural land around them also are aware that similar phenomena are occurring elsewhere. How accurately are we tracking the aggregate effect of all of the disaggregated land-use decisions? Are the SCS statistics on urban land for 1958, 1967, 1975, and 1977 correct, or are we observing only measurement errors? One strong impression that we carry from the National Agricultural Lands Study is the need to improve the nation's systems for inventorying and monitoring natural resources.

Objective Inquiry in Adversarial Settings

The NALS raises important issues of process as well as fact. Can special analyses of agricultural land adequacy, or other controversial policy issues, be assured of objectivity? Many interested parties have a stake in the conclusions and recommendations of such inquiry. Payoff can be in the form of expanded bureaucratic turf, larger budgets for particular agencies, public sanction of particular tools for constraining local development, reduced taxes on rural properties, or personal enhancement. Absent a strong and neutral oversight body to shield researchers and assure that professional procedures are followed, their work is vulnerable to influence, to misrepresentation in the public media, or to being withheld entirely from the public.

Should this occur, the tradition of science is to wait until the work of scientists and scholars elsewhere erodes the credibility of those accounts. When there is momentum for political action, this process may take too long. Misguided policies, programs, or executive orders may result. Procedures for immediate repudiation are less well-established. Absent effective quality control of accounts of scientific inquiry, a loss of public confidence will rob science of its ability to guide public decisions. No short-run payoff can compensate for such a loss of national steerage.

On the Power of Macroeconomic Linkages to Explain Events in U.S. Agriculture: Discussion

Robert L. Thompson

I am very pleased to see a paper on the macroeconomic setting of agriculture in the 1980s on the program. We agricultural economists tended to take a provincial sectoral or partial equilibrium view of the world until events of the early 1970s forced us to recognize that there exist some strong linkages between the agricultural sector and the rest of the economy. We found that agriculture's small percentage of the gross national product (GNP) generated, and of the labor force employed, did not qualify it for such partial equilibrium treatment after all. Macroeconomists discovered at about the same time that they needed to worry about agriculture. At the time this was realized, no macromodel contained a simultaneous agricultural component, and no agricultural sector model contained simultaneous links to the macroeconomy except through deflated prices.

Gardner's paper contains basically three parts: (*a*) a review of the growing theoretical and empirical literature on the links between agriculture and the rest of the economy, (*b*) some original empirical analysis on the subject, and (*c*) some conclusions and implications concerning forecasting in the 1980s. I will comment briefly on each of the three sections.

Gardner's literature survey contains a useful and fairly complete catalog of the literature which has begun to grow quite rapidly in this area over the past decade. It reveals that much of the work done to date on the interrelations between agriculture and the rest of the economy has had ad hoc theoretical foundations for those hypothesized relationships which in turn have been confronted with data. Agricultural economists who began working in this area of "sectoral macroeconomics" were frustrated when they turned back to their macroeconomic theory to find that it dealt only with a composite aggregate real output of the economy, Y, and aggregate price level, P. Any differential sector impacts of shocks to the system were assumed away. Unfortunately, Gardner's list of theoretical transmission mechanisms that may generate differential effects across sectors is rather short. One alternative would be that of Shei, who has taken a monetary approach to the links between agriculture and the rest of the economy, focusing on differences in marginal propensities to absorb goods from different sectors. This causes differential effects across sectors as consumers attempt to adjust existing real balances toward desired real balances in response to a shock to the system. This is but one possible alternative, and much more is clearly needed to provide more secure underpinnings for empirical work in the area.

In reviewing the existing empirical work, I agree with Gardner that much of the empirical evidence is not strong, and that the same data, appropriately massaged, can support contradictory hypotheses. We clearly have far to go in this regard. The empirical work (i.e., the regression analysis) presented in this paper does provide some interesting perspectives. Nevertheless, the specification and estimation of such single-equation regression "models" without fully specifying an underlying structural model leaves me uneasy. It is not clear to me why "it seems unnecessary to strive for a fully specified model." Without this, the specification ends up quite ad hoc, and the basis for including or excluding certain variables is not clear.

More problematical is the failure to clearly define the hypothesized lines of causality, and to delineate clearly which variables are exogenous and which are simultaneously determined with the dependent variable in the re-

Robert L. Thompson is an associate professor, Department of Agricultural Economics, Purdue University.

gression. To me, at least, it is not attractive to refer to inflation or recession as exerting a causal influence on agricultural prices. Agricultural prices are a component of the general price level and are simultaneously determined with all other components. Both respond to shocks to the system such as a change in the money supply.

If one wishes to estimate the reduced-form equation for one endogenous variable, its correct specification is clear after specifying the structural model. This also would help avoid having to resort to terms like "quasi-exogenous." It is not clear to me that all variables on the right-hand side are sufficiently exogenous to apply OLS regression in this case. Before the present approach is followed, it would at least be desirable, following Sims, to apply the available tests of exogeneity rather than assuming that all right-hand side variables are at least quasi-exogenous.

A couple other points which need to be made concerning the empirical analysis:

(*a*) The quasi-stepwise regression procedure in tables 2 and 3 is not terribly appealing. If there is such a thing as a "correct" conceptual model underlying the specification, all but one of these sets of results suffers from specification error and their coefficient estimates should be biased.

(*b*) In deriving his measure of "anticipated inflation," Gardner assumes "quasi-rational expections," to use Nerlove's term, on the part of consumers and employs an ARIMA model to generate his measure of anticipated inflation. However, there do exist survey data collected by Livingston (see Carlson) on actual inflationary expectations which could have been used. This would have avoided having to make any assumptions about economic agent's rationality or quasi-rationality in their formulation of inflationary expectations.

While Gardner's results provide some interesting insights, I would make a plea for more structural modeling of the interactions between sectors including monetary linkages. Two recent theses—by Shei at Purdue and Hughes at Texas A&M—have made starts at general equilibrium modeling of these linkages. Shei's work emphasized monetary linkages and Hughes', the financial market linkages. Much more needs to be done.

Finally, turning to Gardner's conclusions and implications for the 1980s, I do not find the evidence nearly as compelling as he does that the classical dichotomy between real and nominal prices holds. There are very good reasons, as he points out early in the paper, to expect the effects of monetary shocks on prices to be nonneutral across sectors, at least in the short run. As Bordo has pointed out, the necessary conditions for neutrality to hold are stringent. "If monetary changes were perfectly anticipated—and if all prices were perfectly flexible and we were to ignore distribution effects . . . *as well as* the effect that the expected rate of inflation will have on the real rate of interest and on cash intensive relative to other goods . . .—then, the introduction of new money would not produce any 'real' effects" (p. 1089). Furthermore, Barnett recently applied several causality tests to the relation between money supply and the ratio of food to nonfood components of the CPI. His results showed a significant positive causal link from money to relative prices with a five-month lag. No causality ran the other way (p. 108). He also found strong causal links running from money supply to nominal agricultural prices and none the other way. This goes against those who argue that the inflationary effect of real shocks, such as a crop failure comes from *ex post* validation of the resulting price increase by the monetary authority.

From the available evidence, I reach the opposite conclusion from Gardner—that if we utilize agricultural sector models which are fit with deflated prices to project real agricultural prices and then apply separate projections of the overall rate of inflation to "reflate" those values, we are destined to miss the mark in our nominal price forecasts. Moreover, results such as those of Barnett cited above suggest that there are some potentially serious problems with deflating our data series to "remove the effects of inflation" when doing econometric modèling, for example. If monetary shocks affect nominal prices differently, the analyst may actually be perverting the data series by deflating by a price index, thereby biasing the coefficients estimated from such series.

Agricultural Land: Adequacy of Acres, Concepts, and Information: Discussion

Philip M. Raup

The approach taken in the National Agricultural Lands Study to the question of the adequacy of agricultural land is full of hidden agendas. Little wonder that the conduct of the study generated sharply conflicting interpretations of past trends and future prospects. Brewer and Boxley's (hereafter BB) report from the trenches of that conflict gains value from its immediacy and invites reflection upon some of the unresolved issues that haunted the study from the beginning.

A primary concern emerges from the evident inadequacy of statistical data on shifts in land use. This is illustrated by continuing confusion in the interpretation of land use data when classified as "rural," "agricultural," "farmland," and "cropland."

The NALS *Final Report* (p. 2) says "the most recent available data show that about 3 million acres of agricultural land are converted each year to urban and built-up uses—of this 3 million acres an estimated 675,000 acres is from the 413 million acres classified as existing cropland."

These data for 1967–75 come from the *Potential Cropland Study,* published in 1977 by the USDA. That study does not call the 3 million acres "agricultural land." Instead, it refers to the converted acres as "rural" land. This improper use of "agricultural land" to characterize rural land is repeated on p. 13 and in table 5 of the NALS *Final Report.* The correct figures (from the *Potential Cropland Study*) are again cited in the text, but the incorrect use of the designation "agricultural land" is retained throughout the *Final Report.*

Since the figure of 3 million acres lost to agriculture annually has acquired widespread currency, it is important to set the record straight. Table 1 shows that the (nearly) 3 million acres converted annually were "rural" lands, of which 30% was not "agricultural." Only 23% (683,000 acres) came from "cropland," and of that, only 606,000 acres (21% of the total) were converted to urban use. The National Agricultural Lands Study has introduced confusion when it could have promoted clarity in interpreting admittedly deficient land-use data. BB treat this issue, but they could have been more emphatic in stressing the extent to which cropland losses have been overstated by a media and agency preference for shocking statistics. We are not losing 3 million acres of farmland annually, as the media now almost universally report.

A further distortion imbedded in the NALS data that BB analyze grows out of confusion between the physical and the economic supply of land. Data on physical supply are given economic interpretation by the use of current prices and this generation's tastes and preferences. These time-specific data then become the basis for long-run projections. The effect is to freeze the supply of land in terms of current patterns of use. This is contrary to all historical evidence.

This view of the land base has been reinforced by the analytical procedures used to project the demand for land. Most of the discussion of the adequacy of agricultural land has drawn upon partial equilibrium analysis for its theoretical support. Much of the argument in favor of policy measures to preserve agricultural land also reflects a Ricardian view of the "natural and indestructible powers of the soil." In this view, the supply schedule for agricultural land is fixed. In conventional economic graphics, it is a vertical line, unresponsive with respect to price.

The significance of the distinction between a physical and an economic concept of land availability is suggested by the following quotation from the NALS *Final Report.* "There are nearly 14 million acres of prime land in the Northeast, more than in either the eight Mountain states or five Pacific Region states" (p. 20).

Note the likely influence of proximity to markets, accessibility, and related cultural

characteristics in the definition of "prime" land. This points up the fact that projections of land requirements must be based on economic weights which in turn are the determinants of what is "agricultural land," "farmland," or "prime land." These are cultural concepts, and they have been remarkably prone to change.

The most portentious assumption on which the NALS rests, and on which I would have welcomed more discussion from BB, is the assumption of constant real prices for food in all projections. This assumption loads the dice. There can be no meaningful economic projection of land requirements if price is assumed to have no effect upon the economic supply of land.

The assumption of constant real prices for food forces all adjustment in supply and demand onto the supply side. This is supply-side economics with a vengeance. The assumption also implicitly involves a continuation of the present consumption mix, as well. These two assumptions preclude any adjustments to land shortages by shifts in the demand for food. This seems highly unrealistic.

The possibility of adjustments on the demand side is discussed briefly on pages 44–46 of the NALS *Final Report*, but no quantitative estimates are made. In effect, demand is treated as an exogenous variable.

A concluding lesson imbedded in this battle dispatch from BB can be posed as a question: Should researchers take into account the fact that publicists want to report shocking statistics? If the statistic is unremarkable, there is no story. In the same vein, political leaders like to scare people. Fear is apparently a more effective motivation than reason.

This is augmented by the growth of the "hunger business." We have a number of organizations that were created to fight hunger. The mission of these organizations, and the jobs of the individuals involved, depends on finding hunger or the threat of hunger. These forces create an information-disbursing system that rewards exaggeration of any threat to food supplies.

BB make no reference to the fact that the majority of the U.S. population is now remote from biological processes. The percentage of the population without any direct contact with agriculture or food production has followed an exponential growth pattern that parallels the lily pond example. We have suddenly generated a population that does not understand the system by which food is produced and can be

panicked by threats of scarcity. This is the background to the National Agricultural Lands Study.

It is regrettable that these hype-oriented pressures for spectacular statistics have obscured the real problems associated with growing competition for agricultural lands. In seeking to dramatize the problem, the NALS has weakened the credibility of nationally funded research undertakings. This seems to be the main lesson to be read out of the Brewer-Boxley paper.

Commercial Agriculture in Historical Perspective

W. W. McPherson and Max R. Langham

Achievement is a pleasant spectacle when it has been made in spite of obstacles.
—Edwin Ware Hullinger

Our session title suggests that agriculture in the "Old South" can be treated as an entity.[1] To do so requires such great generalization that one soon realizes that much of what is said about modern agriculture in the South can be said about other agricultural regions of the United States. That is as it should be since forces from our political economy which induce adjustment in southern agriculture are also those which affect all agriculture.

Unique features of the "Old South" include the purpose and organization of the initial settlements by Europeans and the influence of these features on subsequent developments. Initial settlements employed systems of indentured servants and slaves to produce products for export to Europe. These features have made the adjustment problems in the South somewhat different and probably more difficult than those elsewhere.

We consider the "Old South" to include those areas in which the slavery system prevailed prior to the Civil War. It includes most of the states of Virginia, North Carolina, South Carolina, Georgia, Alabama, Mississippi, Louisiana, Arkansas, Tennessee, and Kentucky. Parts of Maryland, northern Florida, eastern Texas, and central Missouri were in the Old South, but are excluded here for we are working with data at the state level. For convenience, we have also used regional data as reported for three of the USDA Farm Production Regions—Appalachian (West Virginia, Virginia, North Carolina, Kentucky, and Tennessee), Southeast (Alabama, Georgia, South Carolina, Florida), and Delta States (Arkansas, Louisiana, and Mississippi).

We begin with an historical sketch of the Old South to provide a background of how southern agriculture has been transformed from early settlements until the 1940s. We then look at post-World War II changes and conclude with some speculation about the future.

Early Settlement

Attempts to colonize the South in the seventeenth century were for the purpose of producing products for export to Europe—rice, indigo, tobacco, forest products, and cotton. "The typical institutions—servitude, slavery, the plantation system, and the credit system—were not peculiar to the South nor established by the English race" (Gray, p. 301). Throughout the West Indies, Central America, and South America, the French, Spanish, Dutch, and Portuguese nations engaged in the establishment of similar economic enterprises under similar institutional systems. According to Gray (p. 341), these enterprises were in part the outgrowth of nationalistic ambitions but were promoted and made possible by investors from the nobility, gentry, and bourgeoisie who were essentially interested in deriving profits from investments. But, these colonial enterprises were unprofit-

Florida Agricultural Experiment Stations Journal Series No. 3197.

[1] Such works as Nicholls, and Strand and Heady, and USDA publications, *Farm Costs and Returns* and *Economic Indicators of the Farm Sector*, reveal the inter- and intrastate complexity of the agriculture of a region that extends across states.

able largely because of unfamiliarity with this new environment and difficulties of communication and administration from across the Atlantic.

Land settlement for profit was then attempted by subordinate associations of capitalists. This approach failed also and private plantations followed. These private enterprises "had the advantage of experience with the new environment and the opportunity in some cases to acquire at small cost the lands, improvements, and equipment of unsuccessful colonizing agencies. With the development of regular trade, the planter was provided not only with market outlets for his products, but also a means of procuring on credit the requisite servants, slaves, and equipment" (Gray, p. 341).

Farming Systems and Agricultural Growth to the 1860s

Traditional farm enterprises included cotton, a dominant crop throughout the Old South; tobacco in Virginia, the Carolinas, and parts of Kentucky and Tennessee; rice in South Carolina and Georgia; and sugarcane in Louisiana. Cotton and tobacco were the major exports. Corn was the major subsistence crop—it was the primary feed for work animals and subsistence livestock and was widely consumed for food. These crops were highly labor-intensive. Estimates of the annual man hours per acre for about 1800 and 1840, respectively, are as follows: cotton, 184 and 135, and corn, 86 and 69 (McElroy, Hecht, Gavett, p. 3). The use of slaves was a system in which landowners were able to acquire labor for working areas in excess of what the owner's family could cultivate. Hired labor was not a feasible alternative since moving to the frontier and working one's own land was an option for free persons.

In 1850, the ten states that we include in the Old South contained 34% of the total population and 91% of the slaves in the United States (U.S. Census Office, p. 248). The U.S. population was 14% slaves compared to 37% in the Old South. Among the ten states, slaves as a percentage of total state populations ranged from 22% in Kentucky to 58% in South Carolina.

Labor, obviously, was the limiting factor of production during this era. The acquisition of additional slaves was a means of rapidly expanding commercial output for export to Europe so long as additional lands were available. By 1860, westward expansion of cotton production had moved well into Texas and Missouri. While growth in output and wealth was taking place, the degree of inequality of income distribution also was increasing because slaveholders were able to expropriate any surplus over bare subsistence produced by the slaves. Ransom and Sutch (p. 4) estimated that the distribution of output on large slave plantations in 1859 was as follows: interest and depreciation on capital, 7.7%; salary of management, 3.4%; land rent, 35.7%; food, clothing, etc. for slaves, 21.7%; and expropriation by slave owner, 31.5%.

Two farm organizational systems were in operation: (*a*) the small one-family farm on which the operator and his family provided most of the labor, and (*b*) the plantation on which labor was provided by slaves. There was a wide range in the sizes of farms worked by slaves, from those with a few slaves to those with hundreds. One-family farms occupied the less productive lands and had poorer access to the infrastructure, such as transportation, communication, and education. They were largely self-sufficient with small quantities of output sold to meet low cash expenses.

The number of slaveholders (319,143) was equal to 60% of the total number of farms (534,800) in 1860. However, the distribution of slaves among slaveholders was highly skewed. About 50% of the slaveholders owned five or fewer slaves each and, as a group, 10% of the total number of slaves. At the other size extreme, 1% of the slaveholders also held 10% of the slaves.

There have been several attempts to measure the economies of scale in cotton production during the slavery period. (See, for example, Ransom and Sutch, pp. 73–78, and Gray, pp. 462–80.) There is no reason to believe that economies of scale existed beyond very small levels of production at the farm level, for only simple hand and animal implements were used. Economies in ginning would occur up to the capacity of a gin unit, and possibly in marketing and financing up to rather large outputs. However, the main factor that contributed to the growth of the plantation system was the ability of the landowner-decision maker to expropriate the surplus produced by slave labor.

The main technological factor that influenced agriculture in the Old South prior to

the Civil War was the invention of the cotton gin in 1793, which reduced processing cost dramatically and increased farm-level demand. This event occurred at a time when the prices of rice, tobacco, and indigo were declining and plantations were facing serious difficulties. In 1793, the South produced 10 thousand bales of cotton and exported 4 thousand; in 1810 production had increased to 178 thousand bales and 124 thousand were exported (Vance, p. 42). Production of cotton in 1860 was 3.8 million bales. These rather amazing increases in production were accomplished by employing more labor and traditional inputs on additional acreages of land. Of total U.S. production in 1860, the Old South produced about 90% of the cotton, 100% of the rice, 72% of the tobacco, and 100% of the sugarcane. Thus the Old South was export-oriented throughout the slavery era. International forces were also operating on the input side as capital markets were based largely in England.

Sharecropping Era, 1860s to 1940s

Immediately following the Civil War, plantation owners attempted to reestablish operations by hiring freedmen for wages.[2] However, low cotton prices (due to a release of cotton stored during the war) and serious droughts in 1866 and 1867 resulted in a sharp drop in wages paid. These decreases in wages ranged from 7% in South Carolina, where wages were lowest, to nearly 40% in Mississippi (Ransom and Sutch, p. 65). Plantation owners and hired workers were displeased with the wage labor system and it was very rapidly replaced by the sharecropping system—a system in which both landowner and sharecropper had a vested interest in seeing the crop through the harvest. By 1880 only 9% of the agricultural land in crops in the Cotton South was cultivated in units that could be considered plantations worked with hired labor (Ransom and Sutch, p. 87).

Ransom and Sutch (p. 7) estimated that, on the average, a slave who became a sharecropper had an increase in welfare of 80% to 105%

provided an opportunity for "poor whites" to work on the better lands of the plantations. Apparently this opportunity was a superior alternative for many white families. In 1935, there were 368,406 black sharecroppers and 347,846 white sharecroppers in the whole South. In the Old South, there were 338,000 black sharecroppers and 279,000 white sharecroppers. The black sharecroppers accounted for 48% of farms operated by blacks and 14% of all farms in these states. The white sharecroppers accounted for 16% of all farms operated by whites and 11% of all farms. All tenant classes included 45% of the whites and 79% of the nonwhites.

Social status was identified with land tenure status, from lowest to highest: hired laborer, sharecropper, share tenant, cash tenant, and landowner, and among landowners social status varied directly with acreage owned.

The sharecropping system reached a peak in the early 1930s and began to decline rather rapidly in the late 1930s. From 1935 to 1940, the number of white sharecroppers declined 25% and nonwhites 17% as migration from farm to nonfarm employment accelerated. This labor adjustment was due to acreage allotments on cotton, tobacco, and peanuts—major crops in the sharecropping system—and to increasing off-farm opportunities.

In 1940 there were nearly 22 thousand plantations (defined as multiple-farm units on which 5 or more farm families, including at least 1 cropper or tenant family, are regularly employed), containing 242 thousand farm units—11% of all farms (U.S. Dep. of Commerce, 1940). These farms produced 28% of the cotton harvested. Also, 42% of all farms were classified as subsistence farms—defined as farms on which production for home use was the major source of income. In the remainder of the United States, 27% of the farms were in the subsistence category.

Throughout the sharecropping period, the land per farm family changed very little. The production systems for traditional crops of cotton, tobacco, and peanuts for cash and corn for subsistence were essentially ones in which inputs were combined in fixed proportions of labor, land, mules, plows, hoes, and other traditional inputs. The number of mules in the Old South began to decline after 1935

substitution of tractor power. The introduction of tractor power in cotton and tobacco production lagged behind its use in grain production. Peak manpower loads in the production of cotton and tobacco occurred during harvesting and, in the early stages of mechanization, tractor equipment that would substitute for manpower in harvesting was not developed. Also real labor costs, related to the social constraints on the outmigration of blacks (especially discrimination in education and lack of acceptance in many occupations), lagged in the Old South. The Old South had only 7% of all farm tractors in 1930 and 6.3% in 1940. However, by the early 1940s farm wage rates were beginning to rise faster than other costs as the migration of workers from sharecropper and other tenant families accelerated.

With the deterioration in soil fertility under continuous row cropping, the use of chemical fertilizers was an important factor. From 1932 to 1937, 51% to 58% of the commercial fertilizer used in the United States was applied on farms in the Old South.

Cotton acreage and production reached a peak in the United States and in the Old South in the period 1926 to 1930. This region's share of acreage and production between 1911–15 to 1926–30 dropped from 57% to 48% and from 63% to 57%, respectively. The most rapid increases occurred in new areas of Texas, Oklahoma, and Missouri. The Old South's shares increased in 1935–40 as a result of the historical base used to calculate acreage allotments under the agricultural adjustment program. At the same time, the expansion of cotton acreage in California and Arizona was getting underway.

Five-year average yields of lint-cotton fluctuated from a high of 201 pounds per acre in 1911–15 to a low of 151 pounds in 1921–25. Soil erosion and the boll weevil and later the pink boll worm were major factors that affected yields. The boll weevil entered Texas in 1892; by 1903 it had spread over most of Texas to the Louisiana border; by 1912 it had crossed Oklahoma, Arkansas, Mississippi and was halfway into Alabama, and by 1922 it covered the entire southern cotton belt (Ransom and Sutch, p. 173). In Louisiana, Mississippi, Alabama, Georgia, and South Carolina, the averages of the first four years after infestation compared to the four years before infestation showed reductions of 27.4% in acreage and 31.3% in yield (Ransom and Sutch, p. 175).

Cotton prices were highly influenced by the international market and there were wide fluctuations. Exports that reached a peak of 10.9 million bales in 1927 dropped to 3.3 million in 1939. The 1930–34 price of cotton was 51% of 1925–29. The price of food grains, which dropped by 50%, was the only price that fell relatively more than the price of cotton. Thus it should not be surprising that the cotton and wheat areas were able to achieve a unification in political support—they had many problems in common, such as being heavily dependent on the export market, low prices and subsequent accumulation of large carryover stocks. In 1939, the carryover of cotton exceeded annual production for the first time in history.

Tobacco was second to cotton in terms of cash income produced in the South. Although the average U.S. acreage of tobacco was only 4% of that for cotton in 1926–30, the farm value of tobacco was 22% of that for cotton. In the Old South the income from tobacco relative to cotton increased from 17% in 1911–15 to 32% in 1926–30 and to 61% in 1935–40. Soil conditions for tobacco are more restrictive than for cotton; the Old South production was concentrated in the Atlantic Coastal Plain and the Appalachian areas. North Carolina and Kentucky continuously produced about 70% of the farm value of tobacco from the Old South, but their shares have changed because of the increased demand for cigarettes relative to other uses of tobacco. In 1911–15, Kentucky produced 43% and North Carolina 28%; in 1935–40, North Carolina produced 48% and Kentucky 23%. Acreage of tobacco harvested increased in all but one five-year period from the Civil War until 1926–30. Subsequently, acreage was reduced by allotments. There is no indication of a trend in yield per acre until the reduction in acreage in the 1930s.

Sugarcane production was essentially limited to Louisiana until the late 1920s when production was started in Florida. Production increased consistently from the Civil War until 1898; thereafter there were wide fluctuations. The peak year between 1870 and 1935 was in 1904 with 803 million pounds of raw sugar, and the low year was 1926 with 96 million pounds.

Soil, water, and temperature requirements limited rice, another one of the early settlement crops, to a rather small geographic area. Early commercial production was mostly in South Carolina and Georgia. By 1890, Louisiana had surpassed South Carolina as the leading rice-producing state. Subsequently, as cotton became more competitive, rice production

moved out of South Carolina and Georgia and expanded in Arkansas and Texas (Holder and Grant, pp. 1–3).

Peanuts is a more recent cash crop of importance in the Old South. In 1933–42, there was an annual average of 3.0 million acres planted in the United States, of which 1.1 million were picked and threshed. Eighty-three percent of the total acreage and 89% of the picked and threshed acreage were in the Old South; the remainder was in Texas and Oklahoma.

In summary, the early agriculture of the South was based on trade. Indeed, plantation agriculture would never have developed without a strong European demand for tobacco, indigo, and cotton. Between 1910–14 and 1936–40, the value of cotton and tobacco exports ranged from 48% of the U.S. total agricultural exports in 1921–24 to 66% in 1936–40. In 1905–09, 65% of the cotton production was exported. This quantity dropped to 40% in 1935–39.

Economic forces combined so that agriculture in the Old South expanded rather continuously from the Civil War until the late 1920s. In the 1930s, in the face of reduced exports and low prices, the Agricultural Adjustment Administration (AAA) played a major role in the reduction of acreages.

In the next section we look at agriculture in the modern South. There are indications that the South's, and indeed U.S., agriculture will again face greater dependence on international forces and greater risks.

Modern Era, 1940s to Present

During the last of the 1930s through the 1960s, the Old South and the producers of the "basic" commodities (cotton, tobacco, peanuts, and grains) elsewhere in the United States were somewhat insulated from the international markets via price supports and acreage allotments. There was an acceleration in changes, especially in the Old South. With the development of mechanical power and equipment for all operations from land preparation through harvesting, chemical weed control, and decreased supplies and increased costs of labor in agriculture, sharecropping as an institutional arrangement and source of labor and mules as a source of power disappeared in the late 1950s and early 1960s. Thus the Old South essentially disappeared.

Number and Size of Farms

The number of farms in the South has decreased more rapidly than in any other major region of the United States. During the period 1950–60, the South lost 40% of its farms. From 1960 to 1970, it lost 48% of those remaining (U.S. Dep. of Commerce, 1980, p. 688). By 1980 there were 626,500 farms in the 10 states of the Old South, with an average farm size of 203 acres. This size compares to 244 for the Corn Belt (Illinois, Indiana, Iowa, Missouri, and Ohio).

During the five years 1974–78, farms with sales of under $2,500 decreased in number in contrast with the rest of the United States. The largest size group (sales above $100,000) increased 48% and the $2,500–$9,999 group increased 19%. The data suggest a growing bimodal distribution of sizes in both the United States and the South. The lower peak of the bimodal distribution seems to be forming at somewhat higher sales levels in the South in contrast to the rest of the nation. The categories are consistent with a pattern of small, part-time farms supplemented with off-farm income and large, full-time farms. This pattern is also consistent with the trend of more farm family income coming from nonfarm sources—52% during the 1974–79 period compared with 31% in 1950 for the United States.

Inputs

The basic trends in input use in the South cannot be distinguished from the rest of the nation or, for example, the Corn Belt. Nonpurchased inputs (mainly land and labor) have declined sharply relative to purchased inputs. The purchased inputs increased as capital in the form of equipment has been substituted for labor, and improved seeds, fertilizer, and pesticides have been substituted for land. The index of interest payable per acre in U.S. agriculture has increased thirtyfold since 1945, sixfold since 1967. Some of the increase is due to increased interest rates but most is associated with increased capital use.

Fertilizer use per acre (especially nitrogen) in the three-region South has been heavier than in most other agricultural regions (USDA 1981a). This use is associated with high valued crops and older, more marginal soils. The agriculture of the South also uses about three times as much pesticide and 17% more total

energy per crop acre as the non-South (USDA 1977, p. 22). It is a high cost agriculture and one of considerable risk. As a consequence, land used for crops in the South has been more variable than in the rest of the United States or, for example, the Corn Belt. Cropland moving out of production in the mid-sixties suggests that the southern region has relatively more marginal soils than in the rest of the country.

Labor use data in agriculture suggests a large release of surplus labor to nonfarm employment during the 1950s and 1960s. Labor use in the South remains higher per crop acre than in the rest of the country: in 1945 versus 1979, the hours per acre were 68 and 13 in the three-region South and 16 and 5 in the non-South. The difference is in part due to the fact that some crops grown in the South—especially tobacco—remain labor intensive and in part to smaller average size farms which utilize smaller-scaled equipment.

Output

Farm output in the Delta region, as defined by USDA, has shown more growth than on U.S. farms. Growth in farm output in the Southeast region has been similar to that for the nation and the Corn Belt; the Appalachian region has lagged other regions. Since 1945, acres of corn, cotton, peanuts, tobacco, and hay have decreased. The acres planted to corn and harvested for hay declined as animal power declined. Corn acreage in the Old South decreased from 25.3 million in 1934–43 to little more than 7 million in 1978. Cotton acreage declined largely because of a comparative advantage in the Southwest. The newly developed mechanized power and equipment and chemical weed control was much better adapted to the large irrigated farms in California and Arizona, the large farms in Texas and Oklahoma, and the Delta areas than to the rainfed, smaller, and, frequently, hilly farms in the Southeast. In the Old South, cotton has been reduced essentially to the Delta areas. Georgia, the "heart" of the Old South with 4.8 million acres of cotton in 1911–15, had only 111 thousand acres in 1978. Peanut and tobacco acreage declined in large part because of supply control programs increased and the acreage of timber on southern farms has declined. In terms of production, peanuts, soybeans, and wheat have increased while corn, cotton, and tobacco have declined (USDA 1980).

Indexes of farm output indicate that livestock output has grown more rapidly in the South than crop output. This result is in contrast to what has happened in the United States in general and in the Corn Belt. Cattle, poultry, and egg production have been the big gainers. Hog numbers are down over early post-World War II years and milk production has declined 40% over the past thirty years.

Productivity

The Old South has an image of a poor agricultural region of small farms. This image derives in large part from the sharecropper era and the plight of the "Cotton South" during the boll weevil infestation. The index of farm productivity indicates that the agriculture of the Mississippi Delta has outperformed U.S. agriculture and that of the Corn Belt in terms of relative change. The Southeast and Appalachian regions have performed about the same as the Corn Belt and the country in general (USDA 1981b).

Yield increases of crops of primary importance to the South and the fertilizer use data suggest a progressive innovative agriculture; for example, peanut yields in Georgia have increased by a factor of 4.8 since 1945. Cotton yield in Mississippi have increased by a factor of 1.9, and tobacco yields in North Carolina have increased by 1.8. Although not directly comparable, soybean and corn yields in Illinois have increased by factors of about 1.8 and 2.8, respectively, during the same period, and cotton yields in California have increased by a factor of 1.5.

The Old South has made considerable progress but it still contains many poor farmers. There are in all regions great interfarm variations and this is perhaps more true in the South than in other regions. Small farms in terms of acreage mean a relatively low equity base. On 1 January 1979, the equity per farm in the South was only 25% that of the average farm in the remainder of the U.S.—$85,300 compared with $354,000. This low resource

Low net returns mean less funds for investment purposes, and the cycle of relatively small units is perpetuated.

Institutional Factors

In terms of human capital investments, the South remains behind. In 1976, about 57% of the population above eighteen years of age graduated from high school in the South compared to 67% in the United States. Expenditures in public schools per pupil are relatively low and only Virginia ranks in the upper half of the states on the basis of expenditure per pupil in average daily attendance (U.S. Dept. of Commerce 1980).

Earlier we suggested that the agriculture of the South was a relatively high risk enterprise, and we agreed with Schuh that risks in U.S. agriculture are increasing. Historically, the South has effectively used agricultural programs to maintain or increase income and to reduce risks. A greater proportion of cash receipts plus value of home consumption in the South came from government payments during the fifties and sixties than for agriculture outside the South. In 1945 and since 1975, this proportion in the South was lower than in the non-South.

We hasten to point out that government payments are an imperfect measure of net effectiveness in the use of policy. The South also has been placed at a disadvantage by policy. Perhaps the best example was when the Southwest was able to obtain public investments in water project development which enabled that region to obtain a comparative advantage in cotton production. The distributional aspects of this policy are particularly disturbing because the advantage went to large farms at the expense of small farms.

The body politic of the South has recognized a payoff to policy and developed power by exploiting the tenure system in Congress. Tobacco politics stand out. The result is a contradiction in policy, with the USDA encouraging production at a time when tobacco use is being discouraged by the Department of Health and Human Services.

There is evidence that the agricultural sector in the South is exercising power in state legislatures to obtain funds for research and extension activities. For example, in 1979, the state appropriations in Arkansas, Louisiana, and Mississippi for extension work and for state agricultural experiment stations reported research exceeded appropriations in the midwestern states of Illinois, Iowa, and Missouri. Collectively, the three southern states outappropriated the three midwestern states by 30%. On a per farm or per capita basis, the South out-appropriated the midwestern states by a factor of 3.

Concluding Remarks

Agriculture today is characterized by a set of increasing international linkages. These strengthened linkages are most apparent in the commodity markets. Indeed, one only has to look at U.S. agricultural exports, which have grown to the $40 billion range, to be amazed at this rapid development during the last decade. Schuh has argued effectively that changes in the national and international financial markets are also increasing the number and strength of ties between the agriculture and nonagricultural sectors in an international arena.

Schuh also has argued that growing interdependencies between agriculture and nonagricultural sectors have increased risks in agriculture and that national and international economic policies will do more to condition what happens to agriculture in the future than will traditional commodity programs.

While the international arena is now looking more like the pre-1930s era, the position of the Old South has changed. In 1935–40, cotton and tobacco accounted for 66% of the total value of farm exports. These two crops accounted for little more than 10% of the total in 1978, and a much smaller share of the cotton was produced in the Old South.

Every agricultural region has its problems, but in addition to problems that face agriculture in general, the South perhaps experiences more biological risks than many other parts of the nation because of its warm, moist climate which is attractive to pests, and, except in the Delta, because of its older, more leached soils.

There probably will be some further migration of farm labor to nonfarm employment. But as many persons seek less congestion, and in many instances a warmer climate in which to live, labor markets are created which provide nonfarm employment for resident farm labor. We expect this market for surplus farm labor to become an increasingly important mechanism for adjustment and labor migration that requires moving to an urban setting, less

important. This adjustment mechanism will increase further southern agriculture's interdependence with the nonfarm sector.

Population migration to the Sun Belt has placed greater demands on the indigenous resource base in parts of the South. In these places, water, noise, space, and nonpoint pollution problems will occur increasingly at the interface of the farm and nonfarm sectors. These trends, too, will add to risks in southern agriculture as migration to the Sun Belt continues.

Agriculture of the South effectively used commodity policies from the 1930s to reduce price and income fluctuations. What happens to its agriculture in the 1980s will, by and large, depend on the technological and institutional mechanisms which are created to accommodate adjustment to its more risky environment. It may be that expected net income to farmers will increase sufficiently to make elements contributing to risk seem less important. This may be the case if the international demand for food shifts faster than new technology and resources can shift supply. In recent years, such a scenario seems more realistic than it did in the mid-1960s. If relative food prices increase, U.S. consumer interests may take a more explicit role in agricultural policy issues. U.S. consumers may find it to their advantage to encourage policies that increase agricultural output internationally as well as at home.

Changes in the Black Community

Paul L. Wall

The Division of Behavioral Science Research at Tuskegee Institute is concluding a followup investigation of Charles S. Johnson's classic study of southern rural blacks, entitled "Shadow of the Plantation." The study was published in 1934. The area selected for study was Macon County, Alabama—one of the "black belt" counties which historically formed the region of cotton culture in the South. It is also the county in which Tuskegee Institute is located. The results of this study provide the base line data for our current restudy of the same area almost fifty years later.

At the time of the original study, the plantation system, under which blacks had lived for generations, was seen as a sick and dying institution, unable to compete successfully with other cotton-raising areas in the world market. The blacks who were the subjects of the study were seen as folk people. Given these conceptualizations, Robert E. Park, in his introduction to *Shadow of the Plantation,* proposes a conceptual framework which guided the study:

> It has been observed that as long as their social institutions are functioning normally, primitive people ordinarily exhibit an extraordinary zest in the life they lead, even when that life, like that of the Eskimo in the frozen North or the pigmies in the steaming forest of Central Africa, seems to be one of constant privation and hardship.
>
> On the other hand, when some catastrophe occurs which undermines the traditional structure of their society, they sometimes lose their natural lust for life, and that euphoria which enabled them to support the hardships of the primitive existence frequently deserts them. (p. xiii)

The demise of the plantation system was seen as one such catastrophe. A recurring theme in this original work is the loneliness, the apathy, and the monotony of life observed among the black tenants who lived in relative isolation on the plantation and farms and who were so completely dependent upon their landlords.

The study is based on 612 families located in eight settlements in Macon County. These families represented about 10% of the black population in the county in 1930. The eight settlements were neither political nor administrative divisions. In their isolation, they represented communities to which the people felt they belonged and where "they lived almost within sight of the passing world, dully alive, in an intricate alliance with a tradition which has survived the plantation itself" (p. 12). Johnson's essential observation in his study is:

> . . . that the Negro population of this section of Macon County has its own social heritage which, in a relatively complete isolation, has had little chance for modification from without or within. Patterns of life, social codes, as well as social attitudes, were set in the economy of slavery.
>
> . . . The strength and apparent permanence of this early cultural set have made it virtually impossible for newer generations to escape the influence of the patterns of work and general social behavior transmitted by their elders.
>
> . . . It is unquestionably the *economic system* in which they live, quite as much or even more than the landlords, that is responsible for their plight (p. 16).

With respect to the people, Johnson observes not one but nine types of family structure: stable old families; families with strong maternal dominance; female heads; male heads of transient families; stable nonlegal unions; nonagricultural families; stable legal unions; disorganized legal unions; stable familes with advanced standards. This range of social groupings was viewed as atypical if the family as a universal pattern is defined as consisting of father, mother, and their children. Furthermore, the family was seen as matriarchal in character (p. 29).

With respect to the economic life of the community, it was essentially agricultural, with the occupation of almost every member of the community old enough to work being that of farming. While there were indeed black farm owners and black farm managers, the

---

The author is a professor of education and Director, Division of Behavioral Science Research, Carver Research Foundation, Tuskegee Institute.

vast majority of blacks worked as tenant farmers and farm laborers.

With respect to shelter, the dwellings that were available to tenant farmers presented a dreary monotony of weatherworn cabins. The physical form varied little; there were few alternative models available to stimulate interest in anything else.

With respect to education, Johnson observes that literacy is not not an asset in the plantation economy. Reading and figuring carry elements of danger to established relationships. The tradition that an education was unnecessary persisted strongly. However, the younger generation at the time of the study saw education for their children as an escape from their own dismal economic plight. But the costs associated with education of the children made the odds formidable ones.

About 25% of the male heads of households were illiterate and about 20% of the 579 women heads—either joint or sole—were illiterate. Almost 50% of the male heads were "bare literates," i.e., they had had from one to five years of schooling. When education is related to income, it is obvious that the more economically successful families were those who were neither illiterate nor possessed more education than the system required or was allowed.

These brief references to some of the salient observations made by Johnson and his colleagues in 1930 reflect the then current external pressures on the plantation system itself. Johnson concludes that "the fate of the tenant is but an aspect of the fate of the southern farmer generally, and the plight of all of those await a comprehensive planning, which affects not merely the South but the nation" (p. 212).

Any investigation seeking to trace out social change requires as a starting point not only base line data but the identification of sources of change as well. Johnson observes in 1930 that changes were occurring slowly and that they could be observed and measured. He includes as sources of cultural penetration into the community, the school, the church, the influence of people educated outside the community, return migrants and exposures to extension and demonstration programs in health and agriculture (p. 209). The latter largely eminated from Tuskegee Institute.

In our current restudy, two types of changes occurring in the area since 1930 have been identified: political/legal changes and technological/material changes.

Among the political/legal changes are the penetrations into the area of larger forces associated with such efforts as the New Deal programs, resettlement efforts as, for example, those associated with launching TVA and the establishment of model farming communities of the "40 acres and a mule" type. In Macon County, some of these efforts were successful while others failed. World War II not only provided cultural exposures for the eligible males far beyond the isolated limits of these rural settlements but also benefits for those returning as veterans in relation to housing and education. More important, this exposure provided them a heightened awareness of prevailing social injustices and the stimulus to redress them.

The case of *Brown* vs. *Topeka, Kansas* in 1954 eventually resulted in the closing of the one- and two-room rural schools, the emergence of a consolidated county school system as well as a system of private, white academies which thwarted efforts aimed at achieving racial integration of public schools.

In 1957, Alabama Legislature Senate Bill #291 became law. It was designed to limit political participation of blacks by eliminating from the City of Tuskegee through gerrymandering, approximately 3,500 black citizens. It would eliminate 400 of the city's 409 registered black voters. This effort to disenfranchise rural black citizens was ruled unconstitutional four years later in February 1961, in *Gomillion* vs. *Lightfoote*.

Three years later, in 1964, the impact of Mrs. Rosa Parks' refusal to relinquish her seat on a public bus to a white passenger sparked the mounting discontent of blacks of their position in a segregated society—not only in Alabama but across the nation.

The 1960s were the years of the Great Society, which ushered in the creation of social programs within Macon County that were to change many patterns of living among the rural black citizenry.

Other observable changes of the technological/material type included an enormously improved county road system, the exposure to mass culture through the medium of television, the availability of rural electricity, propane gas, indoor plumbing, public health facilities, improved housing, and the automobile.

Concurrently, the loss of farm land ownership among blacks continued to increase while the economic base of the state, in gen-

eral, and Macon County, in particular, shifted from reliance on a single staple crop—cotton—to reliance on more diversified agricultural efforts including soybean production and cattle raising.

The decade of the 1970s has been heralded as a decade of change for rural America. Employment opportunities expanded and broadened, a reversal occurred in the long-time trend of rural outmigration, and technological advances in transportation and communication transformed rural life. During this decade, considerable progress was made in the quantity and quality of public facilities and services available to rural people. Despite this progress, rural America continues to lag behind urban America in social and economic well-being as observed in such diverse problem areas as education, health, nutrition, unemployment, civil rights, land retention, and the list continues.

It is true that the annual growth rate of rural areas has averaged about 1.3%—exceeding the rate of growth in urban areas by more than 40%. Rural employment is growing and diversifying with new jobs being created at a faster rate than in urban areas. Rural America is growing, but too many rural residents have failed to benefit from that growth. A disproportionate share of the nation's poor still lives in rural areas and virtually all of the nation's persistently poor counties are rural. Additionally, a disproportionately large number of lower income rural residents are blacks, Hispanics, or Native Americans.

In general, the achievements of blacks during the 1970s have been difficult to assess. It has been observed that sharp differences exist between white and black views regarding the quality of life of blacks in America.

In a 1980 Gallup Poll, 75% of whites thought that during the past decade the quality of life for blacks had gotten better, while 45% of blacks thought it had remained about the same or gotten worse. Proponents of the "dramatic improvements thesis" rely on income and occupational data to support the notion that more blacks are now comfortable members of the middle class. Yet, Vernon Jordan of the National Urban League provides a competing assessment:

> For black Americans the decade of the 1970's was a time in which many of their hopes, raised by the civil rights victories of the 1960's, withered away; a time in which they saw the loss of much of the momentum that seemed to be propelling the nation along the road to true equality for all its citizens.

In our society, advancement is ultimately measured in terms of earned income and, by extension, jobs.

And this brings me to one of the most significant patterns that is emerging in the analysis of the data in our restudy of rural blacks in Macon County, Alabama.

Our sample consists of 199 families and includes socioeconomic data on about 3,000 individuals. Over half of these families lived in still-existing communities that were included in the original study.

With respect to employment, 50% were unemployed, about 27% were retired or disabled, about 17% were employed full-time, and about 3% were employed part time.

While there was greater diversity in the range of occupations, 21% of the men were farm laborers and 25% of the women were farm housewives. The remaining occupations could be classified as service workers, textile workers and nonfarm laborers.

With respect to income, over 70% earned less than $3,000 annually.

In 1959, the total median family income for the State of Alabama was $3,927; in 1969, it was $7,26[illegible]; and in 1975, it was $11,785. However, when these figures are broken down by race, the black to white median income ratio revealed that in 1959, blacks earned 42% of what whites earned; in 1969, 49% and in 1975, 58% of what whites earned.

This inequality seems to be a persistent pattern in the state, and there is no indication that the ratio will differ significantly when the 1980 Census is published.

Fifty years after Johnson's observations, the plight of these rural black families in Macon County, Alabama is still awaiting the comprehensive planning which he concludes is needed—not merely for them, but for the rural South and the nation as a whole. Any effort at comprehensive planning must address the inequality inherent in these persistent, systemic economic forces.

Deregulation and Its Consequences for Agriculture
(Orlo Sorenson, Kansas State University, Presiding)

Impacts of Regulatory Change on Financial Markets for Agriculture

Peter J. Barry

The beginning of the 1980s is a landmark in U.S. financial markets because of changes in the regulatory environment that mark this time. Especially important was passage of the "Depository Institutions Deregulation and Monetary Control Act of 1980" (DIDMC). Also under consideration is liberalization of geographic restrictions on banking and further modifications of regulations for financial institutions. Other issues specific to financial markets for agriculture include passage of the Farm Credit Act Amendments of 1980, a more conservative role for government credit programs, and outside equity financing in the farm sector.

My purposes here are to evaluate the possible consequences of regulatory change for agricultural finance and to consider implications for research and policy. The regulatory environment of the financial services industry is reviewed with emphasis on debt capital for agriculture. Specific regulatory issues then are analyzed, including the distribution of financial services among farm lenders and between private and public channels.

Financial Services and Regulations

The major services provided by financial markets include (*a*) an efficient payments mechanism for transactions, (*b*) a means of allocating and bearing risks, and (*c*) an intermediation system for channeling savings into investment. The intangible nature of these services and related financial assets requires confidence, trust, and stability among the markets' participants in order for financial markets to function effectively. Accordingly, these markets experience considerable regulation for purposes of safeguarding savers and investors, standardizing instruments and practices, modifying competition, responding to imperfections and gaps in financial services, and providing for effective monetary policy. Regulations take many forms: restraints on geographic expansion, as in branching and holding company regulations; mandatory specialization in some services (housing or farm lending, transactions accounts); portfolio diversification through reserve and capital requirements, loan limits and asset allocations; interest rate controls on deposits and loans; special borrowing privileges; fair trade practices; and public programs for credit and insurance.

Regulations yield many positive effects, as intended. However, they also may impose substantial costs on participants in financial markets as changes occur in economic, social, and institutional conditions. Inequities can arise that discourage savings, impede flows of funds, and destabilize fund availability from some intermediaries. Achieving equitable regulations among different intermediaries is difficult. High costs of compliance cause lower efficiency of intermediation. Regulations also have induced financial innovations to circumvent government policies, thus further distorting and destabilizing financial markets.

When these costs of regulations become excessive, as is the case in recent years, the stage is set for substantial regulatory change. Numerous conditions have prompted the current changes. Included are disintermediation problems associated with high inflation and interest rates, increasing competition among financial institutions, new entrants to the financial services industry, new electronic technologies in funds flows, changing methods of implementing monetary policies and attrition of banks from the Federal Reserve System, and disadvantages of small savers.

Peter J. Barry is a professor of agricultural finance at the University of Illinois.
The author gratefully acknowledges the review comments and suggestions provided by C. B. Baker, Michael Boehlje, John Hopkin, and George Irwin.

In financial markets for agriculture, the stresses brought by these conditions, along with strong growth in farm debt, have fallen mostly on smaller banks that are heavily involved in farm lending and on their farm and farm-related borrowers (Barry; Hughes et al.). About half of total farm loans at commercial banks are held by 6,000 or so banks with total assets less than $100 million, in which farm loans comprise more than 25% of total loans. Moreover, the nearly 13,000 of these small banks hold more than 70% of total farm loans at banks. These banks rely heavily on local markets for sources of loan funds and have experienced losses of deposits in times of rising interest rates. Their growth in loan demand has frequently exceeded growth in lending capacity, and they are especially vulnerable to changes in local farm income conditions. These conditions have caused periodic stresses in bank liquidity, large swings in fund availability, and increased financial risks for farmers. One indicator of these stresses is the sharp decline in banks' share of total non-real estate farm debt from a high of 52.2% in 1974 to about 38.3% in 1981.

In contrast, other major farm lenders, like the Cooperative Farm Credit System (FCS), the U.S. government, life insurance companies, and many merchants and dealers, are large in size, regional or national in scope, and organized to obtain nonlocal sources of funds for rural markets. Among these, FCS has become the dominant lender in farm credit markets, holding more than 30% of total farm debt, with federal land banks showing strong growth in real estate debt. Shares of total non-real estate farm debt held by government through the Farmers Home Administration (FmHA), Commodity Credit Corporation (CCC), and Small Business Administration have also grown rapidly, totaling about 22% in 1981, up from about 5% in 1974.

The strong growth in farm loan demand, along with substantial variability in farm incomes, have severely tested rural financial markets as channels through which agricultural banks generate funds. These conditions heighten the need for access to nonlocal sources of funds, especially during times adverse to farm income. However, agricultural banks have had much difficulty in developing this access. Instead, nonlocal funds, from government loan programs especially, have flowed abundantly to agriculture in recent years, thus shifting the balance to heavy reliance on public channels. In this light, the regulatory changes that are occurring will have profound implications for relationships among farm lenders and for the provision of financial services to agriculture.

The 1980 DIDMC Act

The 1980 DIDMC culminated a decade-long process of regulatory review by various commissions, congressional debate, and the financial services industry (Federal Reserve Bank). Major elements of the act include the imposition of uniform Federal Reserve requirements on similar classes of reservable liabilities at all depository institutions, provision for the orderly phase-out by 1986 of interest rate ceilings on deposits, nationwide authorization of interest-bearing transaction accounts, temporary preemption of state usury laws on certain types of loans, immediate increases in federal insurance coverage on deposits and accounts, more liberal investments and lending limits of thrifts, and requiring the Federal Reserve to price competitively its individual services and grant all depository institutions access to these services.

Preliminary appraisals indicate that the 1980 act should have the greatest impact on smaller banks which have greater problems in fund availability and less flexibility in balance sheet management (Miller). Smaller agricultural banks, especially, should gain loanable funds from reduced reserve requirements and should eventually be able to compete more equitably for savings funds in local markets, especially when interest rates are high. Pressure to innovate in acquiring local funds will be lessened during these periods with more market-oriented pricing on loans, services, and sources of funds.

If, however, more equitable access to local deposits comes at much higher interest costs, then smaller banks will be hard pressed to compete in farm lending, even if profit margins are lower because of greater competition. How much the cost of funds will increase as the DIDMC phases in is difficult to foresee. Federal Reserve data show that a relatively high portion of agricultural banks' costs of funds already reflects market factors from growing use of money market certificates and 30-month certificates of deposit, both having ceiling rates indexed to yields on U.S. government securities. Recent studies also indicate that community banks have held their

profit margins through the stresses of 1979–80 and are adjusting successfully to interest-bearing transaction accounts as did New England banks earlier. But, the case could differ for agricultural banks that compete with other farm lenders like FCS and the federal government.

Structural Change in Banking

Conditions now are favorable for significant structural changes in the geographic structure of banking. Federal laws about banking structure reflect an historic concern about undue concentration of economic power, competitive equality between state and national banks, and state sovereignty in setting restrictions. These concerns are expressed in the McFadden Act, which prohibits interstate branching and reserves intrastate branching policies to each state; and in the Douglas Amendment to the Bank Holding Company Act of 1956, which prevents bank holding companies from buying or establishing out-of-state subsidiaries unless authorized by the states. The result is a diverse set of state limitations on branching and holding companies.

A presidential task force has comprehensively studied the effects of these regulations, and in a 1981 report to Congress concluded that the McFadden Act and the Douglas Amendment are "increasingly ineffective, inequitable, inefficient, and anachronistic, and that the existing de facto system of interstate banking should be ratified and further liberalized through a phased relaxation of current geographic restraints" (U.S. Treasury Dep., p. 17). The Report recommends a phased liberalization to avoid serious instabilities, initially modifying the Douglas Amendment and later the McFadden Act.

The report is based on research findings that liberalization (*a*) could improve competition in local markets without significant increase in undue concentration of economic power; (*b*) would increase the range of financial services in local communities; (*c*) would improve banking performance through greater actual and potential competition; (*d*) does not significantly threaten the viability of small banks, the safety and stability of the banking system, or dual chartering; and (*e*) would create more equitable competition between bank and nonbanking institutions. Anticompetitive behavior resulting from geographic liberalization should be offset by greater reliance on antitrust laws, increased potential competition from other banks, and growing nonbank competition.

The report's research findings indicate that smaller, independent banks historically have withstood competition from new bank competitors, albeit with the pro-competitive effects of lower prices for services and lower earnings. Evidence is cited that unit banks in statewide branching states use more of their resources for loans than do similar banks in unit banking states and that average returns on total assets decline with increasing bank size, are highest in unit banking states and lowest in statewide branching, and are higher for banks in non-SMSAs. Factors explaining the survival and prospering of small and medium size banks faced with large, branch bank competition include their location in rural or nonmetropolitan markets where earnings are higher and competition apparently less, their competitive pricing of necessary services often through correspondent arrangements, loyalty of customers, and innovations in operations and policies. These factors are consistent with earlier views that rural unit banks have made important use of mechanisms designed to cope with problems in financing farmers (Brake and Melichar).

Farm Credit Act Amendments of 1980

Passage of the Farm Credit Amendments culminated a long legislative process that yielded new insight on the competitive pressures in farm credit markets. Major provisions in the act, designed to update and improve the operation of FCS, include (Wilkinson): (*a*) authorization for Banks for Cooperatives (BCs) to finance agricultural export activities benefiting U.S. cooperatives; (*b*) reduced requirements in farmer-member eligibility in certain cooperatives financed by BCs; (*c*) provision of Federal Land Banks (FLB) and Production Credit Associations (PCA) to finance more fully the processing and marketing activities of eligible borrowers; (*d*) expanded limits for FLBs on loans guaranteed by a federal or state agency; and (*e*) increased cooperation between FCS, commercial banks, and other lenders.

Most of these changes should have relatively minor effects on financing in the farm sector; however, impacts on nonfarm financing may be greater depending on FCS re-

sponses to the first three provisions. The increased cooperation with commercial banks involves further development of loan participations between banks and PCAs, and new authorization for participations between FLBs and banks. Significant revisions also occurred in the authority for Federal Intermediate Credit Banks (FICBs) to loan to or discount loans from other financing institutions (OFI), including commercial banks, through direct arrangements or agricultural credit corporations. The statute now clearly indicates that FICB services are to be reasonably available to OFIs that (*a*) are significantly involved in agricultural or aquatic lending, (*b*) have limited access to regional or national capital markets, (*c*) have continuing need for supplementary funds for agricultural and aquatic lending, and (*d*) do not use FICB services to expand other types of lending. These revisions are intended to put OFIs in essentially the same position as PCAs in their ability to use FICB services.

How commercial banks will respond to these revisions is uncertain, although FCS anticipates an expanded use of loan participations and OFI discounting as regulations for these programs are formulated. The development of FICBs in 1923 was to provide rural banks with new funds by discounting their agricultural loans. Because FICBs were little used by banks, Congress authorized the establishment in 1933 of PCAs who were also to obtain loan funds from FICBs and who would later gain ownership and control. 1971 legislation also allowed PCAs to participate with banks on agricultural loans. The volume of OFI discounting and bank participations has remained low, amounting in 1980 to about 4.5% of FCS outstanding non-real estate debt. Thus, the renewed interest by commercial banks in using FCS as a source of loan funds, expressed in part by debate on the 1980 act, is set against a long history of relatively low use by banks and differences among the FICBs in their willingness to consider OFI relationships.

In a broader context, the debate on the 1980 act brought to light substantial differences in the regulatory environment for commercial banks and the FCS that influence their competitive balance in farm credit markets (Webb, Barry). Included among these differences were the effects of income tax obligations, ranges of financial services and borrowing clientele, legal reserve requirements and lending limits, geographic restrictions, stringency of regulation and supervision, and access to national financial markets. It is especially difficult, however, to evaluate competitive equality among depository and nondepository institutions using similar evaluative criteria when these institutions also serve different clientele and provide different services.

Government Credit Programs

The recent growth in government's farm lending has softened the impacts of volatile credit markets and variable farm incomes on the farm sector. However, much concern has surfaced about special credit treatment in agriculture, the proper balance between public and private sectors, the degree of subsidy involved, and the resulting tax burdens. Also important are the kinds of farmers involved and the relationships with commercial lenders. A recent study indicates that larger proportions of funds in FmHA's Economic Emergency Program went to farmers with relatively large net worths and strong income potential than occurred in the traditional FmHA loan programs (Hughes et al.). Thus the actual or potential availability of loan funds on concessionary terms from the government encourages farmers to use or to become eligible for these programs, attracts customers away from commercial lenders, and discourages participation of some lenders. Some observers (Lee, Gabriel, Boehlje; Benjamin) suggest the past structure of farm credit markets, including the prominence of government programs, has resulted in overfinancing of the farm sector, thus constraining resource adjustment, shifting risk bearing to the government, and capitalizing the effects of concessionary financing terms into higher values of land and other farm assets.

The new administration has sought to reduce the magnitude and subsidy in FmHA programs and largely return its role to a lender of last resort. Besides the high taxpayer cost of government programs, these changes are also based on stronger financial performances anticipated for the farm sector and more moderate growth in farm debt than occurred in the late 1970s (Hughes, Barry); expanded use of new Federal Crop Insurance Programs for disaster protection; more effective use of loan guarantees in private credit programs, tailored to beginning farmers or other target groups;

and greater innovation by commercial lenders in acquiring loan funds and in countering business and financial risks in agriculture. In contrast, credit supplied by CCC likely will not change much. Their programs represent a sophisticated financial control system that combines buffering of price fluctuations for many commodities with valuable liquidity and flexibility for farmers in marketing their crops.

Implications for Financial Markets and Farmers

Less extensive involvement by Government in the 1980s should enhance farm lending by private sector lenders, especially if long term farm income conditions remain favorable. Moreover, the 1980 DIDMC should enable smaller, agricultural banks to compete more equitably for savings that have been channeled away from local markets. However, competition among depository institutions will increase from the expanded authorities of the thrift institutions. Costs of funds and interest rates on farm loans should remain high and volatile, reflecting closer integration of local and nonlocal markets, greater use of price versus non-price responses by lenders, and continued implementation of monetary policies in terms of monetary aggregates. Agricultural banks that experience high, more volatile costs of funds along with vulnerability to local farm conditions will have strong competition from FCS lenders. Intense price competition will occur in some cases, nonprice competition in others, and participation or discounting arrangements in still others. If competition and high costs of funds severely depress bank operating margins, the press for bank mergers and large size will increase. In any case, smaller banks will continue to need reliable, cost effective access to nonlocal sources of funds. Liberalization of geographic restrictions on banking may offer greater flexibility for tapping nonlocal funds, and also yield pro-competitive effects on bank performance.

Evaluating the impacts of these regulatory changes on performance of financial markets and intermediaries is a rich setting for new research. Especially important are innovations in pricing and funds acquisition, evaluating the impacts of geographic liberalization on farmers and other borrower groups, and exploring the differences between banks and nonbank lenders of the loan-deposit feedback phenomenon and its impacts on pricing policies, terms of competition, and market shares as regulations change. Moreover, interest rates should become a stronger determinant of farmers' loan demand and choice of lender. Banks and PCAs, for example, traditionally were considered to be in segmented markets (Thompson). The narrow spreads between their farm loan rates until the late 1970s meant farmers' loan decisions were largely based on nonprice factors, with banks benefitting from strong reliance on interest-free demand deposits. As table 1 shows, these spreads on gross loan rates have changed sharply (Webb). The wider spread in favor of FCS is attributed to banks' growing reliance on higher-cost time deposits with variable ceiling rates. Moreover, the FCS practice of pricing loans with variable rates that are adjusted periodically for changes in average costs of funds, the average maturity of which likely exceeds banks', moderates the pace and magnitude of their rate changes.

Differences between lenders in rate composition are also important. Table 2 indicates average costs of money, lending costs, losses or loss provisions, taxes, and earnings per loan dollar for banks and FCS lenders in 1979. Bank data are from the functional cost analysis reports on commercial and agricultural loans of 349 banks with total deposits less than $50 million. FCS data are from annual reports for 425 PCAs and 12 FLBs. The data are not strictly comparable because of differences in accounting methods, types of loans, loss treatment, tax omissions for banks, omission of stock and deposit balances, and other features of the deposit relationship. Still, they show important differences for these lenders. Costs of money were a lower proportion of total lending costs in 1979 for banks than for PCAs. Operating costs per loan dollar were higher on average for banks, although substantial differences occur among some PCAs.

The largest difference in rate composition between bank and FCS lenders is in earnings rates. The before-tax return on loan assets for the reporting banks averaged 3.02% in 1979, equivalent to a 34.6% before-tax return on equity for these banks' ratio of equity to total assets. In 1979 banks could sustain these favorable earning rates while remaining competitive with PCA rates on farm loans because of differences in their costs of money. Sharp increases in banks' money costs along with their need or desire to keep earnings rates at

earlier levels appear to explain the widening spread in farm loan rates. Hence, banks' ability to sustain their positions in farm lending under current conditions rests on several factors: reductions in earnings, provision of other financial services, nonprice factors including gains from the loan-deposit feedback, price discrimination between farm and nonfarm loans, and farmers' responses to different levels and volatilities of rates.

The current financial environment also brings new considerations about the funds-generating capacity of rural markets, with emphasis on banks' access to nonlocal funds. The needs for this access—overline loans, seasonal factors, liquidity pressures—continue despite the recent regulatory changes. A recent symposium gave an in-depth look at "Future Sources of Loanable Funds for Agricultural Banks" through correspondent banking, the federal government, the Federal Reserve System, the Farm Credit System, banking in-

novations in balance sheet management, and forming a new intermediation system for groups of banks. Preferences appear strong for developing funds access through commercial channels either by more reliable correspondent arrangements, joint ventures, or other types of direct access to national and secondary markets. However, a strong paradox is emerging in that the most stable, efficient, cost-effective, and farm-related source of funds for agricultural banks likely is the Farm Credit System, which also is regarded as the main competition in farm lending for these banks.

The future may bring increasing need for policy makers to come to grips with relationships between FCS and banks in intermediating funds to agriculture. Regulatory differences cited earlier warrant further study. Moreover, stronger demand by banks for OFI discounting and loan participations would increase and destabilize FCS' own needs for funds, thus jeopardizing their relatively unconstrained access to the national financial markets, especially in current times of short maturities on financial assets. However, designing a new national intermediation system for agricultural banking seems to duplicate needlessly FCS facilities unless it accommodates a broader range of loans.

The recent banking legislation also had no impact on banks' legal lending limits, which often constrain the capacity to finance fully their most valued farm customers. New policies could be considered to preempt limits on farm loans that are protected by commercial or public insurance. Smaller banks could then avoid being compelled by regulation to involve other lenders or decline large loan requests.

Further innovation within banking of new financial instruments, institutions, secondary markets, and loan practices should help resolve the funding problems. Research can play an important role in monitoring new developments, evaluating their feasibility, considering regulatory schemes, and analyzing market performance. Modeling procedures and empirical measurement techniques also are suited to evaluating flows of funds in local markets, loan-deposit relationships, local business activity, and individual intermediaries (Boehlje, Harris, Hoskins). Outside equity financing in agriculture also warrants further attention. Some parts of agriculture have long attracted outside equity through direct investment, limited partnerships, common stock and agency services, with their appeal resting on profit potential and tax sheltering of high incomes. Newer channels are associated with foreign investment, pension funds, life insurance companies, and equity participation loans considered by some lenders. The low incidence of regulation for these channels could change in the future with important implications for the structure of agriculture and its financing.

Evaluating the impacts of financial regulations on the farm sector also provides a rich agenda for future research. Farmers should find farm credit markets more in the hands of private and cooperative lenders who will compete more vigorously for their market shares. High levels and volatility of interest rates will continue to bring high financial risks in the farm sector, although rate variability should partially displace the past variability of fund availability from agricultural banks. Differential loan pricing among farm customers should increase to reflect more fully their credit and liquidity risks and lending costs. Skills in liquidity and risk management must improve in response to added risks in financial markets and curtailment of credit reserves from government programs.

Impacts on the distribution of debt capacity among different sizes and types of farms will depend strongly on their relative skills in risk management. Larger operations likely will continue to show favorable performance, although management and entrepreneurship will be more crucial than government programs. Further growth in size, specialization, and capital intensity of farming operations should impact on the structure of financial institutions by further concentrating farm loan portfolios and favoring the risk bearing advantages of larger, geographically dispersed lending institutions. For banks, the pattern of agricultural financing may follow closely the evolving structure of agriculture with larger farming operations seeking larger agricultural banks. Finally, in aggregate analysis, changes in interest rates resulting from forces in national markets, public policy, and the general economy should become more prominent determinants of capital investment and productivity in agriculture.

Impacts on Agriculture of Deregulating the Transportation System

Marc A. Johnson

The term "deregulation," used in reference to surface transportation, is a useful, one-word slogan representing a significant increase in commercial freedom for the transportation industries. However, the term does not imply an institutional shift from the current, regulated, common carrier structure to a completely unregulated, competitive market structure. When constructing the Staggers Rail Act of 1980 and the Motor Carrier Act of 1980, Congress had no intention to terminate surface transportation regulation. The intent was to loosen the grip of government rules, allowing carriers and shippers to respond more fully to opportunities available in an increasingly competitive market environment.

The purpose of this paper is to assess the likely effects of transportation regulatory reform on transportation opportunities of agricultural shippers and rural communities. This purpose requires consideration of three topics: (*a*) criteria for maintaining economic regulations, (*b*) tests of agricultural transportation markets against the criteria for regulation and (*c*) the legislated regulatory changes. This approach also will provide implications for the effects on agriculture of complete transportation economic deregulation.

Criteria for Regulation

Transport regulation in the United States developed along with public utility regulation. A public utility is considered an "essential" industry with a tendency toward monopoly. As such, utilities are publicly sanctioned and supported as virtual monopolies, protected from competitors in return for public-spirited service. The public utility approach has created a transportation system based on the protected common carrier, including all railroads and most for-hire motor carriers.

The common carrier structure is charged with raising rate levels above cost, distorting relative transport rates, creating associated resource waste and yielding miserably low productivity growth in the transportation industries (e.g., Caves, Christiansen, Swanson; Friedlaender; Levin 1978; Moore; Spann and Erickson; Stigler). However, proponents of regulation anticipate monopoly abuses in a free market structure. Criteria for maintaining regulations are discussed next to provide a test of these conflicting views.

Regulation is the exercise by the state of the power to prohibit or compel actions by persons or firms. Three theories have been developed inductively to explain why the state exercises regulatory powers. First, the public interest theory suggests that the state intervenes to protect the public from market power. Second, the public finance theory argues that the state finances "worthwhile" projects through cross-subsidy where the market otherwise would fail (Posner). Thus, criteria for maintaining transport regulation are to be found in market power and market failure. A third theory, capture theory, states that rent-seeking industries capture the coercive power of the state to protect cartel arrangements, i.e., to protect market power (Buchanan, Stigler). Capture theory is important because railroads and motor carriers have been identified as cartels protected by regulation (Moore, Spann and Erickson, Stigler). However, the theory offers no criteria for maintaining regulations.

Market Power

Market power in transportation may arise when only one feasible shipment alternative is available. This may occur in industries with decreasing long-run average costs where consolidations are continually justified or when

traffic volume will support only one carrier, leaving shippers captive to that carrier (Seneca). Thus, criteria for regulation of market power are two: (*a*) evidence of decreasing long-run average cost over the relevant output range of transportation industries and (*b*) a lack of more than one shipper alternative for a significant number of shippers in the long run.

First, the decreasing cost hypothesis can be ruled out. Trucking has been shown to be a slightly increasing cost industry after accounting for capacity utilization factors (Koenker, Moore, Spady and Friedlaender). The minimum average cost of operation lies at an annual output level near six to eight million ton-miles, suggesting economy in trucking firms with 2 to 5 tractor-trailers. Economies in trucking come not from firm size but from the capacity utilization achieved with longer hauls and heavier loads. Strictly limited entry has left acquisition and merger as the only viable means to achieve longer hauls, thereby forcing mergers beyond efficient firm size to achieve economies of utilization (Spady and Friedlaender).

Whether railroading is a decreasing or constant cost industry is unclear from empirical studies (Harris). However, Spann and Erickson have shown that railroad firm behavior prior to the Interstate Commerce Act was not representative of a decreasing cost industry. Also, a recent empirical study reveals that railroads, like trucks, have an average cost which is largely determined by capacity utilization factors (Harris). Traffic density is a major determinant of average cost; operating a given amount of traffic over a larger network raises average cost.

While the decreasing cost criterion for regulation can be discarded, cost studies show clear efficiencies in capacity utilization. One should look for impediments to capacity utilization which represent barriers to achieving least-cost operations.

The second potential source of monopoly power is where either traffic density is low enough to support only one feasible carrier or access to more than one carrier is restricted. This is the "captive shipper" problem considered critical by some (Shaffer, Breimyer). The criterion for regulation in this case is the competitiveness of transportation alternatives. Competition is the lack of supplier control over price and is reflected in price elasticity of demand for freight services faced by particular transport firms.

Market Failure

The second motivation for regulation is to prevent market failure. This may occur if transportation is largely a public good or if transportation markets yield externalities.

Public goods are those which are nonexclusive in consumption and have zero marginal cost of production. Highways and waterways have problems with exclusion. But this is a user charge and taxation issue. There is no problem excluding shippers from the means of conveyance. The zero marginal cost criterion of public goods also is not realistic in transportation. Marginal cost in operations would be zero only in the case of persistent excess capacity, which would not occur in an uninhibited market (Johnson and Pasour). Thus, the public good criterion for regulation is irrelevant for the operating segments of transportation industries.

Externalities might be another source of market failure where transportation influences are (*a*) beyond the direct concern of carriers and shippers and (*b*) incapable of being accounted for by side contracts between carriers and indirectly affected consumers. Examples given of transportation externalities include local economic development potential, population settlement patterns, fuel conservation, and employment effects (Shaffer). The cross-subsidy approach to handling externalities involves two problems: (*a*) identification of a true externality and (*b*) the relative ability of a centralized agency to perceive costs and preferences.

Identification of a true, Pareto-relevant externality is not possible if one accepts the reality that transaction costs are nonzero in contract negotiation (Dahlman). Access to the ability to bargain allows carriers and consumers of indirect transportation products to consider the benefits and costs of a contract which would internalize the effects, e.g., a state highway department subsidizing a rail branch line to prevent road deterioration anticipated with traffic diversion to trucks. If the parties are free to negotiate and a contract is not struck, this implies not the persistence of externality but the inadequacy of anticipated benefits to cover anticipated costs of negotiation and carrying out a contract. Parties may make mistakes due to imperfect information, but this is a part of the entrepreneurial decision process. For an outside observer to identify a no-contract situation as evidence of persistent

Pareto-relevant externality is to say that the outside observer thinks he knows more about the risks, opportunity costs, and preferences of the participants than the participants themselves do. The roles of government are to establish initial rights and to insure the ability to bargain.

If the inability to identify externality were not enough, consider the relative ability of a central authority to accumulate enough information to solve one if found. A central authority must undertake considerable investigations to understand the situation and the interests involved in an indirect products case, and even then, be left incapable of accurately estimating opportunity costs and preferences (Hayek, p. 524). Also, having to start each case without prior knowledge of specific, local circumstances makes it difficult for a central authority to render timely decisions which permit rapid adaptation to constantly changing market environments.

The criterion for regulation to prevent market failure is the presence of market restrictions on bargaining between carriers and nonshippers. When bargaining is prevented, externalities may persist even in the presence of low transaction and operational costs.

The Criteria Applied to Agriculture

Three criteria for regulation have surfaced in the preceding discussion: (*a*) impediments to capacity utilization, (*b*) competitiveness of transportation alternatives, and (*c*) restrictions on bargaining. Agricultural transportation markets can be evaluated against these criteria by mode of transport. Opponents of "deregulation" have supplied two hypotheses: (*a*) that market barriers to entry and capacity utilization will leave rural communities without adequate truck service, and (*b*) that insufficient competitive shipper alternatives exist to protect agricultural communities from railroad monopoly behavior.

Rural Truck Service

There is evidence that rural communities are being served rather well by trucking services in spite of, rather than because of, common carrier obligations, and that market barriers to entry and capacity utilization are not as great as regulatory barriers. The experience of temporarily exempting fresh dressed and frozen poultry and frozen fruits and vegetables from truck regulation during the 1950s is an exemplary controlled experiment on the price effects of "deregulation" (reported in Moore, p. 59). During the period of exemption, truck rates on fresh poultry, frozen poultry, and frozen fruits and vegetables dipped an average 33%, 36%, and 19%, respectively. A recent survey of the exempt livestock trucking industry shows that service prices are very near USDA-budgeted cost estimates (Hoffman, Boles, Hutchinson). Despite near-cost prices, these firms had the following characteristics: an average life of eighteen years, average capacity utilization in a seasonal business of 94,000 miles per year per vehicle, and an economic average firm size of five tractor-trailers.

Free entry of firms into an industry encourages a competitive environment which affects service quality as well as prices. A recent survey of livestock shippers shows that shippers are generally complimentary of service quality; only 20% of the market has gone to private carriage (Boles). Based on several survey studies, Allen concludes that the quality of less-than-load service to rural communities is due chiefly to the fill-in services of the United Parcel Service and contract and private carriage rather than to the fulfillment of common carrier service obligations.

There appear to be neither economic nor marketing advantages which would give large, national carriers an advantage over local carriers in providing local, rural transportation services. In fact, free entry and removal of specific authority restrictions on commodities, routes, and service points will tend to create lower general rates, a broader variety of rate-service alternatives responsive to shippers' specific logistical demands, and enhanced capacity utilization (Johnson and Tyng; U.S. Senate, pp. 124–28).

Rural Rail Competition

The public interest view holds that railroads are regulated to prevent abuse from monopolistic practices. However, five categories of empirical studies provide strong evidence that there are close substitutes for the services of particular railroad companies, providing both intermodal and intramodal competition. These studies relate to evaluations of (*a*) rail line abandonments, (*b*) seasonal railroad rates, (*c*) rail-barge competition, (*d*) fresh fruit and vegetable rail demand, and (*e*) interrailroad competition.

The first group of studies evaluates the effects of rail abandonments on the grain economies of the Midwest and the Plains (Baumel, Miller, Drinka; Berglund and Anderson; Johnson; Larson and Kane; Tyrchniewicz and Tosterud). Although in a few cases portions of lines studied are marginally viable, the maximum abandonment alternative is usually the most efficient because there are less costly transportation alternatives. These alternatives include trucking, truck-rail and truck-barge combinations, and truck assembly at subterminals for subsequent unit-train shipment. These studies suggest that on rail lines of low density, cross-subsidy inherent in rail maintenance is the only force inhibiting economic adjustment of the grain collection and fertilizer distribution system. In fact, there is evidence that removal of regulatory protection on lines can stimulate adjustment and growth (Miller, Baumel, Narigon).

Seasonal railroad rate feasibility studies, conducted in Oklahoma and North Dakota, found that grain traffic would not be smoothed by seasonal rates because shipment alternatives did not permit rail rates to rise sufficiently to encourage additional storage construction (Shouse and Johnson; Wilson, Hvinden, Cosgriff). Both studies assume historical elevator patronage and uniform rail rate increases, prohibiting consideration of interrailroad competition. In Oklahoma, localized own-price elasticities of demand for rail services during the harvest period ranged from -1.02 to -3.7 (Shouse and Johnson, p. 23). In North Dakota, regional railroad demand is inelastic (-0.629) with an elastic cross-price relationship with truck service (Wilson, Hvinden, Cosgriff, pp. 37–39).

Railroad-barge competition is effective over a broad territory. The truck-barge alternative offers competitive rates (equal or below rail rates) for wheat shipment from the entire state of Kansas, except for the southwestern counties (Babcock, Johnson and Mennem). Barge competition also effectively limits rail rate increases for Kansas wheat moving to eastern flour mills, and truck competition limits rail rate increases for Kansas flour to numerous consumer markets (Babcock). In the Pacific Northwest, the price elasticity of truck-barge grain demand is estimated to range from -1.27 to -5.20, and cross elasticities of truck-barge demand with respect to rail rates are estimated to range from 1.46 to 5.30 (Logsdon).

Fruit and vegetable transportation studies on the West Coast also support the contention that competitive transportation alternatives exist for agricultural commodities. Truck and rail services demanded for movements of western fresh cherries and apples have modal demands which are own-price elastic with mutual cross-price elasticities with other modes which are positive and greater than unity (Miklius, Casavant, Garrod). Early evidence on the effects of exempting fresh fruits and vegetables from rail regulation two years ago shows that rail rates fell, rail volume and market share increased, and considerable railroad management activity has been devoted to creating rate-service options to compete in the cross-country fresh produce transport market (Manalytics, Inc.).

The last group of studies is the most convincing in support of the hypothesis that railroads face substantial competition in rural transport markets. A simulation of "deregulation" strategies applied to 1972 conditions and rates reveals the power of interrailroad competition to limit rail rate increases on agricultural products in the absence of maximum rate regulation (Levin 1981a, b). If rate restraints were removed without dismantling collective rate making, rail rates on field crops would climb 40% to 80% and produce rates would rise slightly. However, with a moderate degree of interrailroad competition, field crop rates would fall slightly and produce rates would plummet.

Two localized investigations reinforce the power of interrailroad competition to limit rail rate increases without regulation. Fuller and Shanmugham observe the effects of rail rate increases for wheat in western Kansas, Oklahoma, and Texas. When all railroads raise their rates simultaneously by 10%, arc price elasticities of demand for rail service in five subregions range from 0.0 to -4.4 (-1.47 for the region). However, when only the dominant railroad raises rates by 10% while other railroads and trucks hold rates and facilities constant, the own-price elasticity of demand for the dominant carrier ranges from -1.2 to -8.7 (-5.6 for the region); cross elasticities with respect to other railroad carriers range from 1.7 to 3.8 (2.9 for the region). In the long run, when river and port storage facilities can be expanded, a 10% rail rate hike would remove railroads from the market.

Case studies for corn and soybeans in eastern and western Iowa yield similar results (Miller, Baumel, Drinka). When corn and

soybeans are kept on the farm for marketing flexibility and all railroads raise rates 20%, farmer cost increases 6.8¢ per bushel in western Iowa and 3.6¢ per bushel in eastern Iowa. But when only the dominant carrier raises rates 20% while other railroads do not change rates, farmer cost increases are only 2.0¢ per bushel in the west and 0.7¢ per bushel in the east. In the latter case, own-price elasticity of demand for the dominant carrier is -4.0 in both Iowa regions and cross-price elasticities with respect to other railroads are 7.0 in the west and 3.5 in the east. The Iowa study suggests that with a flexible marketing strategy, farmers have the capacity to deliver grain to elevators located on railroads with the best rates. This is the source of interrailroad competition.

The preceding summary of evidence, generated in numerous independent investigations using a variety of analytical methods leads to the following conclusions regarding the criteria for regulation: (*a*) internal firm cost economies provide strong incentives toward maximum capacity utilization; and (*b*) competitively priced alternatives to local rail carrier service are broadly available. There likely will be specific instances where service will diminish in small communities and rail shippers will have to cease operations. However, there appears to be no strong evidence to justify maintenance of pervasive transportation regulation for agriculture. Specific complaints of monopoly behavior or discrimination can still be taken to the ICC, the Department of Justice, or the court system.

Regulatory Reforms

Preparations are now complete to evaluate the effects of transportation regulatory reform on rural communities. Regulatory reforms in transportation are chiefly contained in the Railroad Revitalization and Regulatory Reform Act of 1976 (4-R Act), the Staggers Rail Act of 1980, the Motor Carrier Act of 1980, and various initiatives of the ICC.

Motor Carriers

The Motor Carrier Act of 1980 focuses on reducing regulatory entry barriers. The act directs the ICC to streamline the common carrier certification process and to ease the criteria for approval. Fully certificated carriers must prove themselves "fit, willing and able" to serve and that they will serve a "useful public purpose," presumably much less strict than the "public convenience and necessity" standard. Protestors must be directly involved in the type of carriage proposed, and evidence of potential traffic diversion from existing carriers is no longer sufficient to prevent entry. Under expedited procedures, existing carriers can expand their authority to cover more commodities, intermediate delivery points, round-trip routing and larger territories; many specific routing and gateway restrictions are to be removed immediately. Mixing of contract and common carrier loads and exempt and regulated commodities in the same load is permitted to add loading flexibility.

Three motor carrier entry provisions are especially important for agriculture. First, cooperatives can haul up to 25% of tonnage from nonmember, nonexempt commodities, instead of 15%, which improves backhaul potential. Second, more agricultural inputs have been exempted from regulation, including animal by-products not for human consumption, livestock and poultry feed, and agricultural seeds and plants. Third, a new class of "fitness only" carriers has been established for those performing the following services: (*a*) serving a town recently losing a railroad or not served by a regular carrier, (*b*) hauling government property, (*c*) hauling small packaged freight and (*d*) owner-operators hauling food products, agricultural limestone and soil conditioners, and agricultural fertilizer. These services are presumed to fulfill the "useful public purpose" criterion, and applications will be reviewed only on the merits of the carriers' fitness to serve these functions. All three provisions provide flexibility for exempt and cooperative haulers to extend their seasons of operation and to organize backhauls to the country.

Previously, evidence suggested no appreciable market barriers to motor carrier entry or capacity utilization. New regulatory rules greatly reduce regulatory barriers to entry and capacity utilization. Now all classes of truckers can apply for, and expect to be granted, authority to haul the traffic for which they can compete in the market. City to country backhaul potential is much improved, especially for exempt haulers, with relaxation of access to food, feed, and fertilizer. Because truck costs are so sensitive to capacity utilization, eased entry can be expected to reduce trucking costs. Access to traffic and lower trucking

costs will enhance competitiveness within the agricultural trucking industry and place lower rate ceilings on railroads.

Railroads

The Staggers Rail Act of 1980 focuses on railroad-pricing flexibility and protection of bargaining channels. The act sets a minimum rate standard at variable cost and limits ICC jurisdiction on maximum rates to those cases where the railroad has "market dominance." A rate falling below a rate-to-variable-cost ratio threshold is sufficient to show a lack of market dominance. In shipper-initiated complaints, the burden of proof is on the shipper. Consequently, railroads are currently free to adjust rates in a considerable band. In addition, limited liability rates and rate premiums for special car services provide flexibility to construct rate-service options. Rate flexibility provisions already have been used to lower short-haul rates to meet truck competition and to lower long-haul rates for grain.

Three provisions are especially important for agriculture. First, two classes of carriage previously available to motor and water carriers are formally recognized for railroads: exempt and contract carriage. ICC initiative previously exempted fresh fruits and vegetables and piggyback shipments from regulation. Contracts make possible the direct negotiation of specific shippers and carriers for specific rate and service packages designed to shipper and carrier logistical needs.

Second, a pair of provisions stimulates interrailroad competition, previously shown to be very important in market rate control. One provision restricts the activities of rate bureaus preventing discussion and voting on single-line rates and, after 1983, discussion of joint rates by other than "practicably participating" carriers. Another provision establishes a quick procedure by which shippers can petition for reciprocal switching agreements between railroads. This means that shippers in two-railroad towns who are located on only one railroad can obtain access to both railroads with obvious competitive value.

Third, rail abandonment procedures are made speedier than previously, but more market options are made available to shippers and groups who truly value the line. These options included (*a*) carload surcharges on low-traffic lines, (*b*) rail-affiliated truck services to communities losing rail lines (previously truck allowances applied only to communities with rail lines), and (*c*) forced sale of deteriorating branch lines to local groups.

Previously, evidence showed that with moderate interrailroad competition, railroad rate freedom would not harshly affect agriculture, generally. Through rate bureau limitations and reciprocal switching agreements, interrailroad competition is enhanced. Rate flexibility can and is being used to enter new markets offering shippers savings. Contracts and exemptions open a new field of negotiated, tailored rate-service packages to shippers yielding enhanced capacity utilization for railroads and improved service for shippers. Shippers and local community groups are now allowed greater flexibility in bargaining directly with railroads on means to preserve local rail services where options were restricted before. Railroad regulatory reform offers many new opportunities for creative marketing and procurement in agricultural industries.

Conclusion

Transportation regulatory reforms represent opportunities for agriculture. As with any change of rules, there will be cases of individuals losing while others gain as a result of regulatory reform. But evidence does not reveal any fulfillment of the criteria for maintaining regulation in the agricultural transportation markets. These markets are competitive. Cost incentives encourage capacity utilization. The profit motive encourages entry and bargaining for service. Agriculture would be well served if remaining motor carrier entry restrictions and railroad rate limits were removed on a path toward true deregulation.

Regulation has been largely counterproductive for agriculture. A layer of restrictions on competitive market processes has been substantially removed; direct bargaining between firms promotes transmission of clearer market signals. "Deregulation" offers many opportunities for agricultural firms to adjust marketing and procurement strategies to reflect a greater range of transportation price and service options.

Impacts of Regulatory Change on Financial Markets for Agriculture: Discussion

Dean W. Hughes

Peter Barry has done a good job of summarizing recent changes in legislation and discussing the impacts of these changes on the suppliers of agricultural credit. Therefore, I have only a few additional points to make regarding the impact of these changes on the sources of farm credit. I would then like to expand his analysis to discuss more fully their impacts on the farm sector.

Some Additional Market Changes

At least four recent financial innovations not mentioned in Barry's paper are having an impact on rural credit markets. The first is the introduction of financial futures markets, which should allow for some reduction in the anticipated growth in interest rate risks. The second is the emergence of a service provided by financial intermediaries wherein small banks' certificates of deposit are packaged to offer in the national money markets (Illingworth). This service will reinforce the other trends that Barry suggests will more fully integrate rural financial markets with the national economy. The third is that nonmember banks gained access to the Federal Reserve System's discount window with the enactment of the Depository Institutions Deregulation and Monetary Control Act of 1980. Such access may provide a source of credit to some nonmember rural banks that they have not had in the past. Finally, the rapid growth of money market mutual funds has decreased the flow of funds in rural credit markets over the last two years (Gramley). But in the future, as new equilibriums are established and alternatives evolve for rural banks to tap national money markets, this problem likely will decline in importance.

Dean W. Hughes is a staff economist at the Federal Reserve Bank of Kansas City.

The views expressed in this paper are the author's and do not necessarily reflect those of the Federal Reserve Bank of Kansas City or the Federal Reserve System.

Impacts on the Farm Sector

Barry's paper suggests that there will be at least four substantial impacts of recent and anticipated legislative changes on rural credit markets including: (*a*) less quantity rationing (both in aggregate and on the individual loan level), (*b*) higher interest rates, (*c*) more variable interest rates, and (*d*) a decline in the importance of government lending.[1]

A decrease in fund availability problems at rural banks would decrease the likelihood that short-run changes in financial markets would have dramatic impact on the ability of farmers to produce food and fiber. It also would accelerate the concentration of the farm sector. If the laws on branch banking are significantly altered, local banks' capital and surplus limitations may impose fewer restrictions on the size of individual production loans. In addition, one of the automatic stabilizers of farm sector concentration will be removed. In past times of limited fund availability, agricultural lenders' priorities have been to make operating loans first and to postpone farm ownership loans. Thus, farmers deciding to quit during a time of credit rationing would have a difficult time finding buyers who could arrange mortgages. They might then produce for another year and later find their financial position improved. If, in the future, credit is rationed only by interest rates, those who are "creditworthy" (normally those who are already wealthy) will be able to borrow to buy the assets of exiting farmers at all times.

Higher interest rates in rural credit markets will require larger farm incomes. Highly leveraged operations will be faced with higher interest expenses. But the need for higher incomes will not be restricted only to farmers who rely heavily on debt financing. Higher

[1] These impacts are not predictions of the future, but differences caused by changes in legislation. For example, while interest rates may not increase above those currently faced by farmers, they will be higher in the future than they would be if the laws had not changed.

interest rates will be available on the alternatives to investing equity funds in farming, so the entire sector will have to be more profitable. Investment projects will have to be discounted by higher costs of capital, and therefore fewer may be accepted. All else equal, the subsequent slowing of the adoption of new technologies will slow the rate of increase in farm output and farm prices should increase.

An increase in the variability of interest rates can best be analyzed as an increase in financial risk (Penson and Lins, Gabriel and Baker). Two consequences are suggested by such analysis. First, farmers likely will want to reduce their borrowing to some extent. This will add to the slowing of adopting new technologies and may tend to depress the rate of increase in farm real estate values. Second, farmers may try to reduce their production risks. Marginally profitable land which is subject to unusual weather risks may be removed from production. And farmers will likely demand increased coverage from government and private insurance companies. The concentration of the farm sector also will be speeded up by these increases in risk. Large farmers with substantial equity buffers and wealthy nonfarmers will be more willing to accept the increased financial risks than small- to medium-sized farm owners who rely on farm income as their primary means of support.

A sudden reduction in government lending could have dramatic effects on the farm sector. Currently, the federal government holds over 12% of all farm debt. Any program that would rapidly decrease government lending would likely send many farmers into bankruptcy, reducing farm real estate values, and to some extent decreasing farm output. Even if the reductions occur more slowly, such that there is minimal disruption of production and real estate values, there will be an acceleration of the concentration of the sector and an increase in the risks of farming. The Farmers Home Administration (FmHA), the primary government lender to agriculture, must by law lend to farmers who cannot get credit elsewhere. Assuming, then, that their clients truly could not find credit from other sources, a reduction in FmHA lending will lead their borrowers to leave the sector. Because the vast majority of FmHA loans have been made to small farmers, any reduction in their role will increase average farm size (Hughes et al.). A decrease in the commitment of the government to lend to farmers will also increase the risks of farming in an ultimate economic sense. There likely will be an increase in farm failures in coming years as the accumulation of farmers who have been "bailed out" by FmHA over the last few years are allowed to leave the sector. Some normal failure rate probably will then be reasserted.

Conclusions

With few exceptions, Barry's paper does a good job tracing the impacts of recent regulatory changes on the institutions that supply credit to the farming sector. Simple extensions of his analysis suggest that the farming sector itself will be affected in several ways. It is likely that the deregulation of rural financial markets will speed the movement to a more concentrated farming sector. In addition, the adaption of new technologies probably will be slower than otherwise would occur. Farming will need to be more profitable to justify continued investment and to offset anticipated increases in financial risks. And finally, farm output likely will grow more slowly and farm prices increase more rapidly than would be expected if no change in banking regulations had occurred.

Impacts on Agriculture of Deregulating the Transportation System: Discussion

Jerry E. Fruin

I concur with the general conclusions of Johnson's paper. Transportation deregulation was long overdue. Regulation was ineffective and, in some instances, counterproductive to agriculture, rural communities, and the regulated carrier. There will be individual losers as adjustments are made to less regulation, but the total result for agriculture will be positive. However, I have several reservations about the overall thrust of rail deregulation.

Johnson states two justifications for regulation of the transport industry. One is the need for the cross-subsidization of services that the transport firm could not or would not otherwise supply. The other is the argument that the state must protect the public from the market power of the industry. Two examples that the opponents of deregulation use to show that agriculture and rural communities require transportation regulation are then discussed. These are *(a)* that market barriers to entry will leave rural communities without adequate truck service, and *(b)* that insufficient competition exists to protect agriculture from railroad monopoly behavior.

With regard to truck service to small communities, he concludes, and I fully concur, that "free entry and the removal of specific authority restrictions on commodities, routes, and service points will tend to lower rates, improve service, and enhance capacity utilization." The barriers to entry for trucking came more from the regulatory requirements than from market barriers. The Motor Carrier Act of 1980 removed many of these restrictions. The act will have little impact on agriculture and rural communities, and the impact that it does have will be positive. That is also true for airline and intercity bus deregulation. The airways and highways are publicly owned, and freedom to enter a market can provide competition. Rail is different. The roadbed is privately owned. That provides monopoly power.

Jerry E. Fruin is an assistant professor, Department of Agricultural and Applied Economics, University of Minnesota.

Will sufficient competition exist to protect agriculture from railroad monopoly behavior? Johnson concludes that although there may be some harm, there is no strong evidence to maintain transportation regulation for agriculture. He cites a number of studies to back his conclusions, but each addresses specific issues and not the total deregulation package. That package went much further than thought possible two years ago. Consequently, rail deregulation may have gone too far.

I agree with the rail abandonment studies that conclude that the maximum abandonment case is most efficient considering the economic variables studied. However, I am not convinced that the distribution of the economic returns will be equitable. How much of the savings will stay in the rural areas? What will happen to land values 40 miles or more from a subterminal? Will subterminal ownership become controlled by the limited number of regional or national firms that have the access to the capital required to build train-loading facilities and the market power to negotiate favorable contract rates? Do these studies adequately account for the cost of maintaining our road network as grain is moved longer distances to subterminals and the vehicle mix and routes traveled change?

The Staggers Act did not leave the ICC and the states enough discretion on abandonments. There still is no master plan with hard decisions on abandonment versus the rehabilitation of marginal lines. The last branchline in an area frequently will have operating profits after competing branches are abandoned if it is rehabilitated at railroad or public expense, but the ICC cannot force a sensible rationalization of the rail system.

Some of the studies center on interrailroad competition holding down rates. But, will we really have effective interrailroad competition in 1990 with only six or eight major rail systems? Mergers as a method of rationalization are encouraged by the Staggers Act, but we

can no longer be assured of open gateways and joint rates as in the past. Rather, surcharges and combination rates may become the rule. Some of the railroads will have monopoly power over larger areas than envisioned in these studies. We cannot count on barge transportation being as effective in holding down rates in the future. Waterway user charges have been legislated and are now in place. Currently, they have little or no effect on barge-rail competition. However, if full cost recovery is legislated, rails will gain a cost advantage over large areas.

A key feature of the Staggers Act is the legalization of contract rates and the release of the railroads from their absolute common carrier status. Although a number of safeguards were included for agricultural shippers, the end result is that a railroad is free to discriminate, i.e., choose whom it will sign contracts with. These contracts could give a limited number of shippers low-cost volume rates while others pay higher single-car rates. These contracts, once approved, cannot be appealed to the ICC. Clearly, there will be increased concentration in the grain-marketing channel. Time will tell if this is good or bad for agriculture.

An important implication of deregulation for agriculture and for the national economy was not discussed. The combination of rate-making freedom and contract rates will destroy the existing railroad rate structure in the United States. Furthermore, the loss of antitrust immunity for rate bureaus (with which I agree) will preclude such a rate structure from being reestablished. Much of this value-of-service based railroad rate structure is over 100 years old, having roots that predated the ICC. This structure includes provisions like transit rates and port equalization differentials. It had tremendous stability because of precedents established in ICC hearings and supreme court decisions. It was reinforced by protests from affected constituents when even minor changes were proposed. Such stability hindered locational and technological adjustments. For example, there is general agreement that the transit privilege slowed the relocation of the grain processing industries.

The big changes for agriculture resulting from the destruction of the old rail rate structure will be in changed cost and locational advantages for food processing and manufacturing. Consider the impact of changes in the rate structure for sugar on the optimal locations for industries like baking, canning, and confectionaries and soft drinks. The existing structure was defined by the ICC Sugar Cases of 1922 and 1933. This rate structure was designed to "equalize" competition in the Midwest between cane sugar refiners in East Coast ports, New Orleans, and San Francisco, and to allow them to compete with domestic sugar beet refiners. Most of the cane sugar was, of course, from Cuba. This rate structure survived the Great Depression, sugar rationing, consumer acceptance of beet sugar, Castro's takeover of Cuba, and the development of the 120,000-pound airslide car.

The basic rate relationships of the 1933 ICC proceedings were that rates for a hundredweight of sugar shipped from New Orleans or Baltimore to Chicago were equal, the rate per 100 pounds from Philadelphia to Chicago was 1¢ more than from New Orleans, and from New York to Chicago 3¢ more.

Although the sugar rates from New Orleans and Baltimore to Chicago almost tripled from 34¢ to 95¢ during the forty years from 1933 to 1973, the differentials remained unchanged. It still cost only 3¢ more per hundredweight to ship sugar from New York to Chicago than from New Orleans to Chicago. This did not happen by accident. The ICC responded to industry protests each time there was a general rate increase and set the maximum rate increase for sugar equal to the increase from New Orleans to Chicago. The promotion of competition, if it ever did exist, evolved into protectionism.

These rate relationships caused sugar consumers on the East and West Coasts to subsidize midwestern sugar consumers, and caused sugar-using industries such as candy to locate in the Midwest rather than in the coastal sugar-refining centers.

The justifications for low sugar rates from the East to the Midwest center on Mississippi waterway competition. I was always puzzled over that because the commercial barge lines will not even consider hauling sugar. However, I recently found this quote by McPherson (pp. 371–2): "The railroads point out that the suger rates cannot be made higher to the cities on the Mississippi and Ohio Rivers, as they are now at the limit above which the boats would take the traffic." Note the use of the term "boats," not "barges," as that was written in 1909. Also, I have been collecting rates for a sugar substitute, fructose, from Minnesota to locations including Baltimore,

Interrelationships between Spot and Futures Markets: Some Implications of Rational Expectations

Joe H. Dewbre

The view that futures contract prices for storable agricultural commodities are rationally held expectations of subsequent cash prices has been widely accepted since Holbrook Working first explained commodity market intertemporal price behavior in these terms in 1958. Subsequent analyses by Brennan, Weymar, Tomek and Gray, and others adopted and extended Working's interpretation. Yet, despite its acceptance, implications of the rational expectations view have been all but ignored in econometric modeling efforts directed at explaining and predicting intertemporal price relations.

The purpose of this paper is (*a*) to propose an econometric modeling approach that recognizes the role of rational expectation formation in joint determination of commodity cash and futures prices, and (*b*) to explore the implications of such an approach for the following issues:

(*i*) the direction and magnitude of changes in cash and futures prices occurring in response to changes in economic information, and the direction of causality between cash and futures prices; and

(*ii*) the function of futures markets as agencies for forecasting price and the probable forecasting performance of futures contract prices.

Some issues addressed here have implications for all futures traded commodities. The arguments presented, however, relate most clearly to storable, continuously inventoried commodities. The nature of storage behavior and, thus, the relation between cash and futures prices for some commodities—livestock in particular—has not yet been resolved satisfactorily, but these issues are not addressed here.

Working's theory of anticipatory prices (1958) asserts that decisions on cash and futures prices take into account all available and relevant information concerning historical relationships as well as current and expected supply-demand conditions. According to this theory, the current period futures price for a contract maturing in time $t + T$ is the current market expectation of the subsequent cash market price in $t + T$.

With only slight modification, this interpretation can be considered equivalent to the more current "rational expectations" or equally redundant "efficient market" hypothesis. Formally stated, the rational expectations hypothesis (Muth's extended version) asserts that expectations of individual market participants (the subjective probability distribution of price outcomes) tend to be distributed for the same information set about the predictions of the theory (the objective probability distribution of price outcomes). In another interpretation it is simply asserted that economic agents use the appropriate economic model in forming their expectations of future prices. If valid, this latter interpretation has clear implications for the construction of econometric models of futures traded commodities. To explore these implications, we posit a model which assumes rational expectation formation.

An Econometric Model of Cash and Futures Price Determination: A Rational Expectations Approach

The model described here consists of only three equations: a current period commercial demand for stockholding, a current period

Joe H. Dewbre is an agricultural economist at Wharton Econometric Forecasting Associates, Inc., Philadelphia.

The author wishes to thank F. Gerard Adams, George R. Schink, Michael D. McCarthy, and Anthony Haidorfer for their beneficial comments. Especially helpful were discussions with Mark French on the subject of rational expectations. All these gentlemen are associated with Wharton Econometric Forecasting Associates.

aggregate consumption demand relation, and a market clearing identity equation. The equations are conceptualized and are to be estimated in monthly frequency. The logic of each demand equation is discussed briefly, with most attention devoted to the stockholding relation. Some of the ideas are then simplified in a graphic representation of the model, followed by some inferences.

Commercial Stockholding Demand

The dual role of stocks in markets characterized by seasonal production and stockholding tends to complicate the process of modeling such markets. On one hand, current period demand for stocks is usually the major component of current period demand for a given commodity. On the other hand, during most months, beginning-of-period stocks constitute the only source of supply. In this formulation, demand for stocks (supply of storage) depends upon the expected return to storage—the difference between expected future cash price and current period cash price—adjusted for expected storage costs. Expected storage costs, as defined here, consist of opportunity cost on the per unit value of the inventory commitment plus the physical outlay for space rental, insurance, and handling charges. The stock demand equation is presented in functional form below:

$$(1) \qquad Q_t^H = f_1[E(P_{t+1})_t - P_t - C_t],$$

where

$$\frac{\partial f_1}{\partial E(P_{t+1})} > 0, \ \frac{\partial f_1}{\partial P_t} < 0, \ \frac{\partial f_1}{C_t} < 0,$$

and where Q^H is the current period demand for stocks, $E(P_{t+1})$ is cash price expected to prevail in period $t + 1$—current period futures quote for a contract expiring in period $t + 1$, and C_t is one period storage charges—space rental, insurance, handling, and interest charges.

Assuming that current period futures prices represent unbiased market expectations of future cash prices, observed values of futures quotes can be plugged into the above equation for estimation purposes. With other factors being held constant, the demand for stocks is an increasing function of the difference between expected future cash price and current period cash price. Notice also that, consistent with usual requirements for demand functions, the slope of the relationship between demand for stocks and current period cash price is a negative one. Conversely, consistent with the usual requirements for supply functions, the slope of the relation between expected future period cash price and demand for stocks (supply of storage) is a positive one.

Aggregate Consumption Demand

A complete model of consumption demand would include separate equations for each component of current period consumptive demand, e.g., food, feed, and export for grain commodities. For simplicity's sake, the consumptive demand function used here represents an aggregation of these separate demand equations into only one equation. In practice, this would be accomplished by simply adding the separate consumptive demand equations together and then collecting terms. The result would be an equation with total current period quantity demanded on the left-hand side and, on the right-hand side a large number of variables representing current period prices of the commodity in question, of substitutes in feed, food, and export uses, and of commodities which use grain as an input (e.g., livestock). Other variables would measure incomes, exchange rates, other purchasing power indexes, and so on. Labeling all variables except current period quantity demanded and current period price of the commodity in question as Z_1 to Z_N, this equation would appear as

$$(2) \quad Q_t^D = (P_t^{b_1} Z_{1,t}^{b_2} Z_{2,t}^{b_3}, \ldots, Z_{N,t}^{b_{n+1}}),$$

where

$$\frac{\partial Q_t}{P_t} < 0, \frac{\partial Q_t^D}{Z_{i,t}} \lesseqgtr 0, \text{ and}$$

where Q_t is current period aggregate consumption demand, P_t is current period cash price, and $Z_{1,t}$–$Z_{n,t}$ are exogenous variables influencing consumption demand.

Market Clearing

Under the presumption that production is exogenously determined, as would usually be the case within any particular crop year, the final equation in this "mini" model is the standard market-clearing identity or price determination equation:

(3) $Q^{H} = Q_{-1}^{H} + Q_t^P - Q_t^D,$

where Q_t^P is production in period t.

Nothing has yet been said about how $E(P_{t+1})$, the price expectations variable which appears in the stock demand equation, is to be determined. In most commodity models, expected price is some kind of average of recent past prices, either a naive projection of last period's price or some form of adaptive expectation usually based upon a time series of price. Blakeslee incorporates a next year's loan price into an adaptive price expectations formulation. His approach allows an adaptively determined price expectation to be modified by one piece of information about the future—next year's price support loan rate. Houck and Subotnik model the determination of one-quarter-a-head futures prices within the same model that produces current quarter cash prices. Their formulation excludes altogether any consideration of expectations about the future; futures prices in their model are determined exclusively on the basis of current period supply-demand conditions.

These approaches seemingly would deny the rational expectations or anticipatory prices hypothesis which holds that prices (both cash and futures) reflect all publicly available economic information that bears upon their determination. More to the point, these approaches are inconsistent with observed market behavior. It has been shown that information concerning future supply-demand conditions does indeed influence current period cash prices (Pearson and Houck).

In this application, the price value that would be obtained by solving the posited model for the appropriate forward period is used to represent current expectations of that period's price value. A literal interpretation of the rational expectations hypothesis would have commodity market participants deriving expectations of future price as if they were actually solving a model like the one described above for the appropriate future period. In a very literal way this would require market participants to plug into each equation forecasts of each exogenous variable and then solve the complete model for the values of future price and other endogenous variables for the expectation period. Of course there is no requirement under a rational expectations view that market participants actually employ this forecasting procedure, but only that the expectations which they derive be consistent with those that would be obtained by using the model.

In order to draw some conclusions, it is helpful to review the ideas thus far presented in graphic form. Panels A and B (lines CD_1CD_1, D_1D_1, S_1S_1 and FCD_1FCD_1, FD_1FD_1, FS_1FS_1) of figure 1 present an initial equilibrium solution for the model for both a current and a future period. Looking first at panel A, the line CD_1CD_1 represents the current period aggregate consumption demand equation (2) drawn under the assumption that all variables except price are held constant. The line D_1D_1 represents the total of equations (1) and (2), where the difference between CD_1 and D_1 is current period stock demand. The current period supply function is shown as a perpendicular line reflecting the fact that supply available for any single current period is wholly predetermined. In most months this supply will consist entirely of stocks carried forward from the previous period, but even in those months in which production becomes a component of supply, it does so independently of price.

In order to graph the future period consumption equation (panel B, line CD_1CD_1) in the current period it is necessary only to plug in forecast values for future period $t + T$ for all exogenous variables $Z_1 \ldots Z_N$, appearing in the consumption equation (2), and then solve the equation at alternative levels of expected future price. The graphs of the other two lines are not obtained quite so simply. Considering future supply FS_1 FS_1 first, notice that it has some slope with respect to price. This occurs even if the forecast period is too short for a production response to price. This is because expected future supply consists of both expected future production and expected future beginning stocks; but expected future beginning stocks depend directly upon current period ending stocks, which by equation (1) are positively related to expected future price.

Graphing the stock demand function for some future period is made more difficult because doing so requires *ex ante* knowledge of what price expectations in the period $t + T$ will be for an even more distant future period $t + T + 1$. The obvious answer that this would require solving the model for period $t + T + 1$ only begs the question since this, in turn, would require *ex ante* knowledge of expectations of future price for some more distant horizon $t + T + 2$, and so on. One way of dealing with the problem is simply to extend the forecast horizon far enough into the future so that, because of discounting, any change in the level of expected price for the terminal

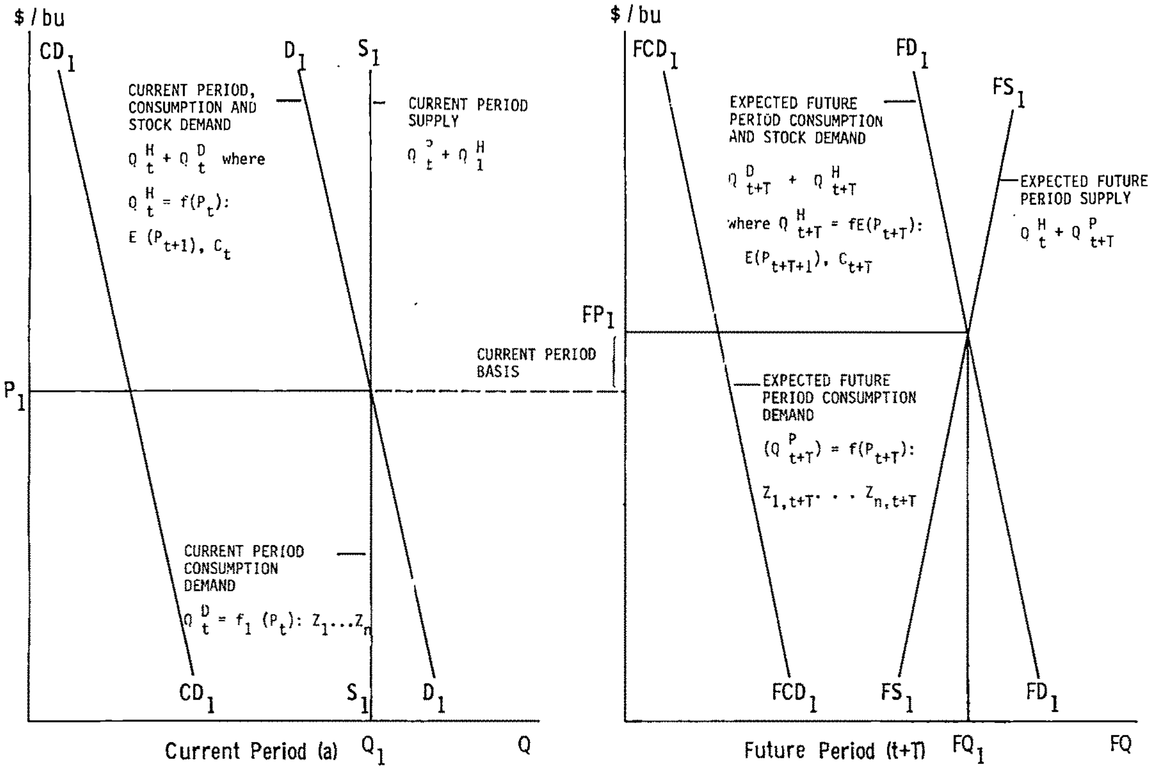

Figure 1. Initial cash and future period equilibrium

period has only a minor effect on any period within the forecast horizon of interest. The problem is resolved here by assuming values for these so-called "terminal" expectations of future price for the $t + T + k$th period. The choice of values for these assumptions is necessarily an arbitrary one, but there are some logically appealing alternatives. For example, forecasts of future agricultural production and prices are published routinely by the U.S. Department of Agriculture (USDA) and other public and private agencies. There is also the notion of a long-run "equilibrium" or normal price. This normal price probably is determined more by the relative (long-run) costs of producing the commodity in question versus alternative commodities than by the near-term stock considerations which so dominate price determination in the model posited here.[1]

It is now possible to trace the effects that changes from the initial equilibrium represented in figure 1 have on current and future period price and quantity outcomes. Figures 2 and 3 show the same initial equilibrium as was shown in figure 1—lines CD_1CD_1, D_1D_1, S_1S_1 in panel A and FCD_1FCD_1, FD_1FD_1 and FS_1FS_1 in panel B—and two alternative final equilibrium solutions obtained by assuming first an increase in expected future period production (figure 2) and second, a decline in current period interest rates (figure 3).

In this model, the causal chain which results in the "final" solution shown in figure 2 proceeds as follows. First, the increase in expected future production is translated into an increase in expected future supply which produces a "first-round" expected future price decrease. Since expected future price is a shifter in the current period stock demand equation, the decrease in future period expected price produces a leftward shift in current period demand for stocks, and a consequent round-one decrease in current period price. This decrease in current period price stimulates an increase in current period consumption and a falloff in current period carryout. The process does not stop here, however, since the decrease in current period carryout

[1] In this application, a forecast of this long-term normal or equilibrium price is to be modified simultaneously with model solutions across near-term forecast horizons. This is to be accomplished by adjusting a forecast of price produced by an annual model for end of crop year stocks generated by the posited short-term model.

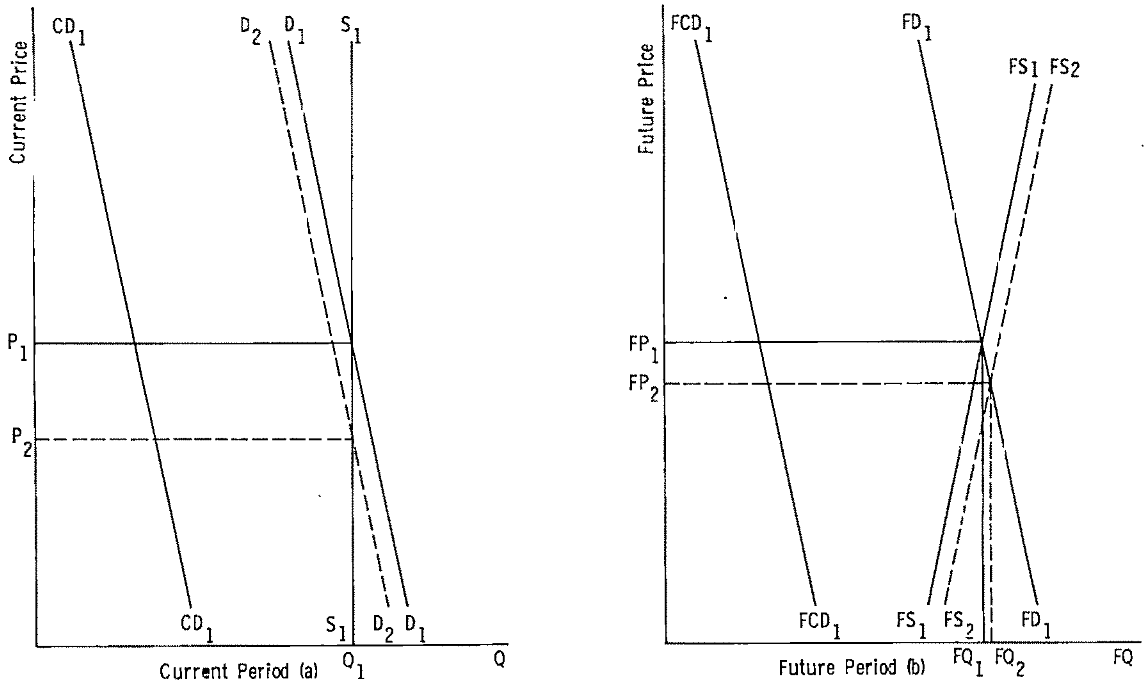

Figure 2. Impact of increase in future period crop expectations upon current cash and futures price

shows up as a decrease in future period supplies. This moderates the round-one future price impact, which in turn moderates the current period stock demand, and so on until the final equilibrium situation, $P_2FQ_2FQ_2$ shown in the figure 2, is obtained.[2]

As an additional example, consider the impact of a current period decline in interest rates, which is not accompanied by a change in expected future period interest rates (figure 3). This impacts initially by reducing storage costs and thereby increasing current period demand for stockholding. This causes a first-round increase in current period price and a rightward shift in future period supply (the increase in stocks carried out of the current period), which results in a corresponding decrease in future period price. The first-round decrease in future period price moderates the initial increase in current period stockholding demand, and thus the first-round increases in current period price as well, and so on until the final equilibrium $P_2FP_2FQ_2$, shown in figure 3, is obtained. Notice that in this final equilibrium, current period cash prices are higher while current period future prices are lower than in the prior equilibrium.

[2] Econometric model solution procedures that correspond to this kind of equilibration are somewhat different from conventional procedures. Anderson and Fair provide good discussions of how standard model-solving routines can be modified to accommodate a rational simulation approach. For readers familiar with standard Gauss Siedel iterative model solution programs, the problem essentially involves creating an outer iterative loop in which the model solves iteratively across entire forecast horizons in a manner analogous to iterative loops within individual forecast time periods.

Inferences

There are two major inferences with respect to the interrelation between cash and futures prices which, under a presumption of rational expectations, differ from conventional views. One of these concerns the way in which futures and cash prices fluctuate in response to changes in economic information, and the other concerns the forecasting performance of futures markets as they have been conventionally evaluated.

Direction and Magnitude of Changes in Cash versus Futures Prices

It is commonly held that changes in information concerning future supply or demand will, for storable agricultural commodities, produce equivalent or nearly equivalent changes in

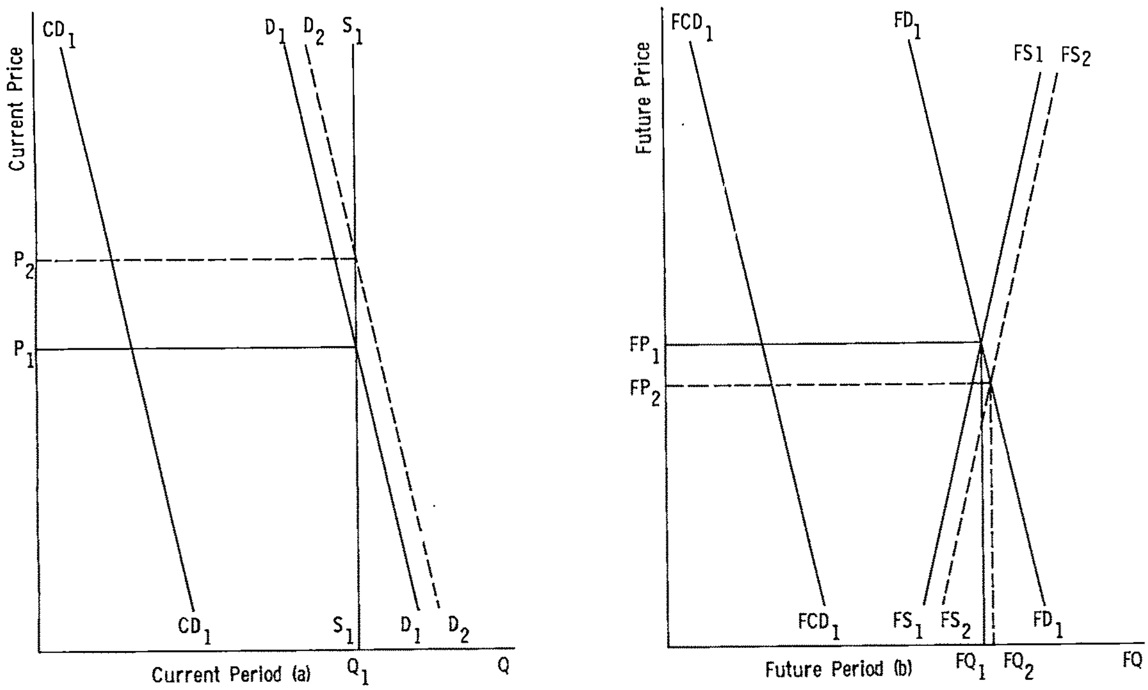

Figure 3. Impact of decrease in current period interest rates upon cash and futures prices

both cash and futures prices. These conclusions can be drawn using either of two frameworks of economic analysis—the supply of storage framework or the intertemporal-interregional price equilibrium framework.

In its usual interpretation, the supply of storage theory asserts that there are two more or less independent components to intertemporal price relationships. The first is the overall level of both cash and futures prices, which moves up or down in response to changing actual and expected supply-demand conditions. The second is price difference or "basis" relations between cash and futures prices and between individual futures prices. According to the usual view, the latter component of cash and futures price relationships, the basis, is substantially determined for any point in time by the level of actual inventories and costs of storage at that point. Working (p. 1255) states, "So far as supplies are concerned, it is only supplies already in existence which have any significant bearing on a current intertemporal price relation." One implication of this interpretation is that changes in expectations concerning future supply or demand conditions produce their price effect exclusively through a shift in the overall level or constellation of intertemporal price relations, leaving price difference or basis relationships unchanged (see Working 1949). That is to say, because of stockholding, any change in expected future supply or demand produces a change in current period price that is approximately equal to the corresponding change in expected future period price.

One can reach equivalent conclusions concerning changes in cash versus futures prices using the familiar intertemporal (or interregional) equilibrium framework (see, for example, Kenyon and Cooper). In this framework, prices for two markets separated in time or geographically, but in which storage (or trade) is permitted, will be in equilibrium when the price difference between them just equates with storage (or transportation) costs. In this model, changes from initial equilibrium in either expected quantities or storage costs will always produce exactly the same changes in both current and future prices.

Both of the above-mentioned theoretical frameworks are widely accepted and have guided much economic modeling. However, if one accepts the rational expectations arguments detailed in this paper, then the usual conclusions concerning the magnitude and

direction of changes in cash versus futures markets are invalid.

Given changes in economic information about the future simply need not produce equivalent changes in both cash and futures prices and, in fact, would be expected to do so only rarely. Clearly, the relative impact that a change in information about the future has on cash and future prices will depend on the time horizon of the information (discounting), the nature of the change (whether it is a change in a component of future demand or of future supply), and upon the relative elasticities of current versus future period supply and demand. Indeed, under quite plausible assumptions about particular changes in information, even the direction of change in cash prices may differ from that for futures prices. The interest rate decline traced in the previous section provides one example.

A related issue concerns the direction of causation between commodity cash and futures prices. The issue of whether futures prices cause or lead cash prices has been at the heart of much of the controversy over futures markets. It is clear from this treatment that causal chains which produce changes in cash and futures prices can run in either direction, depending on the kind of economic information initiating the change. For example, a change in information concerning future period consumption demand (such as an announcement of a trade agreement) would produce its effect on current cash prices through a causal chain initiated by a change in future price. Alternatively, a change in current period consumption demand produces its effect on future price through a causal chain initiated by a change in current period price.

Forecasting Performance of Futures Market

The forecasting performance of commodity futures markets has been the subject of much recent empirical analysis. Results reported in Leuthold, Leuthold and Hartman, and Martin and Garcia pose serious doubts about the accuracy of current period livestock futures contract prices as predictors of subsequent cash prices.

These analyses are all apparently predicated on the questionable assumption that an appropriate test of futures market performance is ability to forecast the future accurately. It is argued here that a more appropriate question is the same one that must be asked of an econometric forecasting model: "Are price changes which occur in futures markets (or are simulated by an econometric model) in response to changes in economic information consistent with economic theory?"

What can be said about the probable predictive performance of current period futures market quotes? One implication of the rational expectations view is that, since for any given point in time futures prices reflect all publicly available information, observed changes in prices (cash and futures) through time are due exclusively to unanticipated changes in information. Further, since over time such information becomes available randomly, the resultant observed price changes are random (serially uncorrelated). It follows directly that forecasts of future cash price taken from the futures market are unlikely to be very accurate for anything but the shortest time horizons. Furthermore, the longer the forecast horizon, the more time is allowed for randomly occurring changes in information, and the poorer are such forecasts likely to be. Thus, empirical results which appear to confirm this, such as those reported by Leuthold and Hartman and Martin and Garcia, can hardly be taken as an indictment of futures markets.

Interrelationships between Monetary Instruments and Agricultural Commodity Trade

Robert G. Chambers

During the last decade agricultural economists have devoted increasing attention to the macroeconomic aspects of agricultural problems. Indeed, a recent presidential address to the American Agricultural Economics Association (Tweeten) centered on the macroeconomics of agriculture. Given the currency of the monetary approach to macroeconomics, it is not surprising, therefore, that there is also a growing interest in the effects of monetary instruments and monetary phenomena on agricultural commodity trade. In this paper I shall discuss what I feel are some of the most pertinent issues that researchers must address in this area. Before we proceed too far with our discussion, it is important to define what I mean by a monetary instrument.

Perhaps arbitrarily, I reserve the term "monetary instrument" for those macroeconomic variables which are primarily determined within domestic or international monetary markets. Obvious examples are the level of the money supply, interest rates, and exchange rates. I justify the term instrument by noting that as far as the agricultural sector is concerned these variables are, by and large, predetermined. For example, the levels of the money supply and interest rates in the United States are to a large extent determined by the policy of the Federal Reserve. Similarly, the price of the currency—the exchange rate— is ultimately determined by the demand and the supply for the currency and thus at least partially by governmental policy.

The first step in any attempt to outline research needs and goals is an identification of what has been done in the past. Although the literature on the macroeconomics of agriculture is fairly large and rapidly expanding, Eckstein and Heien, Lamm, Schuh (1976), and Tweeten are important examples, relatively little attention has been given to the effect of monetary instruments on agricultural trade. What attention has been given to this area of research has revolved mainly around the role of exchange rates in determining agricultural exports and prices. Thus, it is logical to start our discussion with a brief survey of the literature on exchange rates and agriculture.

Previous Investigations

Like most relatively new areas of research where there is not even a common agreement on what are the important problems, the relationship between exchange rates and agricultural trade has been the subject of a somewhat controversial literature. Schuh (1974) was among the first to suggest that the magnitude of the exchange rate could have important implications for agricultural trade. He suggested that maintenance of an artificially overvalued dollar for much of the postwar period had depressed U S. agricultural production, exports, and prices while artificially boosting the domestic demand for U.S. farm products. The argument behind Schuh's paper was simple and to the point; the maintenance of an overvalued dollar made U.S. agricultural exports relatively unattractive abroad. By artificially dampening overall demand for agricultural commodities, the exchange rate policy of the United States induced not only a lower level of agricultural exports but also lower domestic agricultural production.

Following Schuh's article, there appeared a series of theoretical and empirical studies on the effect of exchange rates on agricultural commodity trade (Grennes, Vellianitis-Fidas, Greenshields, Kost, Bredahl, Bredahl and Womack, and Chambers and Just 1979). The

Robert G. Chambers is an assistant professor, Department of Agricultural and Resource Economics, University of Maryland.

This is Scientific Article No. A-3025, Contribution No. 6088 of the Maryland Agricultural Experiment Station.

general tenor of several of these papers was that the importance of the exchange rate may have been overlooked for a long time, but past negligence should not be an excuse to overemphasize its current importance. Given the number and variety of these papers, it is impossible to do them justice within the confines of this presentation. What was (and remains) important is that they represent serious attempts by agricultural economists to investigate in detail the relationship between truly monetary variables and agricultural commodity trade. Remember that prior to 1973 the official U.S. exchange rate was a monetary instrument in the truest sense. It could be raised or lowered by the U.S. government. In fact, much of the original interest in the exchange rate followed President Nixon's decision to devalue the dollar in 1971.

By the time agricultural economists concerned themselves with the exchange rate, it was no longer a monetary instrument in the purest sense. In late 1973, the United States adopted a floating (albeit dirty) exchange rate system. Thus, much of the discussion on the relationship between the exchange rate and agricultural trade now centered on what actually happened after the United States devalued in the early 1970s. As is usual with economists, each party to the discussion had its own version of the truth and, in retrospect, perhaps too much time was spent arguing about the theoretically plausible size of the effect of the devaluation on agricultural commodity trade. Altogether too little time was spent on the next logical step in the progression—the investigation of the effect of the current determinants of the floating exchange rate on agricultural commodity trade.

Researchers acquainted with the literature on balance of payments and exchange rate analysis know that this next step was not easy since even experts in balance of payments analysis do not agree on the most appropriate method for modeling exchange rate determination. However, the then recently nascent monetary approach to the balance of payments and exchange rate determination suggested an important direction of further re- identity of the balance of payments with the difference between the demand for and the supply of a currency. If there is excess demand for a currency, then there exists a positive balance of payments; excess supply implies a deficit. The monetarists, therefore, argue that since the balance of payments is essentially a monetary phenomenon, it is best and most easily explained in terms of money and asset markets. If the exchange rate is functionally related to the payments situation of a country, then the monetary approach would suggest that the exchange rate is best explained by monetary phenomena.

Shei appears to have been the first to attempt a thorough investigation of the effect of monetary phenomena on U.S. agriculture. In his doctoral thesis, he constructed a compact, empirical, general equilibrium model of the U.S. economy. The model was simulated to investigate the impact of the money supply and the exchange rate on the agricultural sector of the economy. Shei's results indicate that the money supply has more important effects on U.S. agriculture than the exchange rate. Unfortunately, even though Shei's overall model was general equilibrium in nature, he treated the exchange rate as predetermined. Thus, a potentially important component of the adjustment process—the causal linkage between the money supply and the exchange rate—was ignored.

Chambers and later Chambers and Just (1981) developed empirical models of the interaction between the level of the money supply and the agricultural sector with an endogenized exchange rate. In point of fact, the exchange rate determination process provides the only direct link in the models between the level of the money supply and the agricultural sector. Thus, while a shortcoming of the Shei model is overcome in these studies, it must be recognized that they are less thorough in the specification of other potential linkages than the study by Shei.

Using dynamic multiplier methods on their empirical models, Chambers and Just (1981) estimated that the long-run elasticities of wheat, corn, and soybean exports with respect

little doubt that their results would be altered if a more complete set of linkages were specified. The Chambers and Just model also contains a significant nonlinearity which had to be replaced with a Taylor series approximation to permit multiplier analysis. Hence their results represent local approximations which might not be valid over a wide range of sample values.

Quite recently, Barnett, Bessler, and Thompson have completed an empirical examination of the causal linkage between the level of the U.S. and international money supplies and a variety of agricultural prices. This work is impressive in that it represents, to my knowledge, the first attempt to use Granger causality methods in investigating the relationship between a monetary instrument and agricultural policies. Previous work (e.g., Chambers and Just 1981) had simply assumed that the relationship existed and then postulated an empirical model to measure the effect. The results of Barnett, Bessler, and Thompson suggest "a strong causal relationship between money supply and U.S. agricultural prices . . ." (p. 10). At the same time, they found "no evidence of agricultural prices causing money supply . . ." (p. 10). Epstein and Chambers have also found evidence of a causal relationship between the exchange rate and the level of exports of several agricultural commodities using Box-Jenkins and Granger causality techniques. Thus, while existing empirical studies may not be conclusive, they seem to point in the direction of an important link between monetary instruments and agricultural commodity trade.

At this point it seems appropriate to discuss the recent work of Van Duyne. Although not directly concerned with the effect of monetary instruments on agricultural commodity trade, Van Duyne's analysis specifically recognizes linkages between agricultural commodity markets and asset markets. Using a two-country, two-commodity (an agricultural and a manufacturing good), three-asset (domestic money, foreign currency, and commodity stocks) model, Van Duyne analyzes the effects of disruptions in the agricultural sector (such as bad harvest) on prices, exchange rates, and trade flows. Thus, his purpose is somewhat different than that of the present paper in that he is interested in the effect of agriculture on the general economy while we are mainly interested in the effect of certain monetary macroeconomic forces on agricultural commodity trade. However, the fact that he has specifically modelled linkages between the monetary and agricultural sectors is important and should provide a fruitful direction for further research.

Problems for Further Research

Although the level of the money supply is likely the single most important monetary instrument in the U.S. economy, there are numerous other monetary instruments (such as interest rates) which ultimately affect agricultural commodity trade. Furthermore, the somewhat spotty research in this area is in need of a widespread extension before it can be integrated into the main corpus of agricultural trade analysis.

Perhaps the first order of business in this area is the establishment of a satisfactory theoretical model of the interaction between monetary factors and agricultural commodity trade. The key to any analysis of this sort will be the manner in which linkages between the markets are specified. To see why, consider the following simple one-market, two-country model. Aggregate demand for agricultural commodities in the home country is represented by $D(p,M)$, where p is the price of the aggregate commodity and M is the disposable income. Aggregate supply is taken to be a function of the aggregate price and the interest rate (r), $S(p,r)$. If we use asterisks to differentiate the foreign country from the home country then trading equilibrium can be represented as

$$E(p,m,r) + E^*(p^*,M^*,r^*) = 0, \tag{1}$$

where $E(p,m,r) = D(p,m) - S(p,r)$. To complete the model, assume that the law of one price prevails, so that we can write $pe = p^*$ where e is the exchange rate between the domestic and the foreign currency. For the moment we presume that e is arbitrarily fixed by the governmental authorities.

We can use the model described by (1) to consider, say, the effect of a decision by the Federal Reserve to tighten credit and drive up interest rates—not unlike what we have witnessed over the past year or two. Differentiating partially with respect to r and expressing the result in elasticity form yields

$$\epsilon_r{}^p = - \frac{\epsilon_r{}^E}{\epsilon_p{}^E + \epsilon_{p^*}{}^{E^*}}, \tag{2}$$

where ϵ_j^i is the elasticity of i with respect to j. Under usual circumstances, the denominator of (2) is negative and ϵ_r^p, therefore, has the same sign as ϵ_r^E. Since ϵ_r^E represents the shift in excess demand of the home country associated with a change in the interest rate we can expect it to be positive. Thus, an increase in the interest rate yields an increase in price as denominated in the home country's currency. At the same time, the price as denominated in the foreign country's currency must also rise.

Turning to the direct effect on agricultural commodity trade, let us suppose from now on that the home country is the exporter of the agricultural commodity $[E(p,M,r) < 0]$. Using this assumption and the result in (2) establishes that in elasticity terms the comparative static effect on quantity traded can be written as

$$\frac{-\epsilon_r^E\,\epsilon_{p^*}^{E^*}}{\epsilon_p^E + \epsilon_{p^*}^{E^*}}. \tag{3}$$

By our earlier arguments we see that expression (3) is negative and that the amount of the commodity traded decreases as the interest rate rises.

Of course, these results are quite intuitive and can be shown using graphical techniques without resorting to the calculus. Consider, for example, figure 1, where I have represented the system graphically (assuming linearity). Panel (a) represents demand and supply conditions in the home country, while panel (c) represents demand and supply conditions in the foreign country. Panel (b) represents the excess supply and excess demand curves (assuming the home country is the exporter) derived from (a) and (c). Assuming that $e = 1$, we originally have trading equilibrium at price level P and quantity traded Q. Suppose that the interest rate rises; farmers are now likely able to afford a smaller debt burden and thus likely produce less at every price. The domestic supply curve shifts inward to, say, S'. The shift in S forces a shift from ES to ES' which in turn leads to the higher price of p' and lower amount traded Q'. We see immediately that the amount of the agricultural product consumed in the foreign country declines while foreign production rises. Domestic consumption falls while, in general, the effect on domestic supply is indeterminate.

Suppose, however, that the exchange rate is not fixed but instead, like the U.S. dollar, adjusts to forces in the international money market. One of the key determinants of the exchange rate in the monetary and asset market approach to exchange rate determination is the relative rate of interest between trading partners (Isard). In a world where monetary assets can move across international borders, one expects an increase in the interest rate to attract investment capital from abroad thus improving the country's payments position.

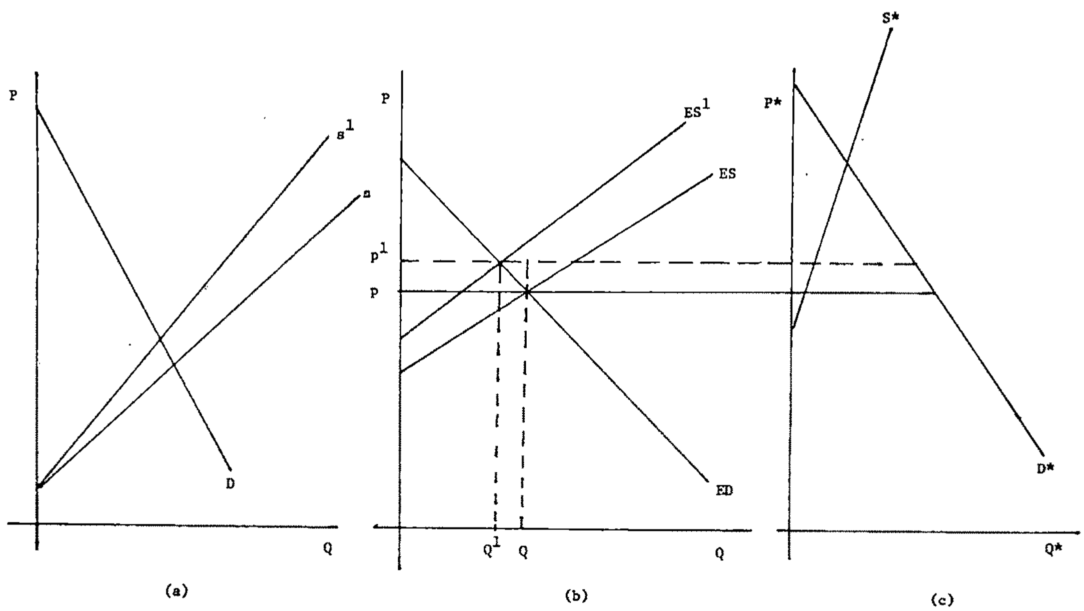

Figure 1. Effects of interest rate change on foreign trade

Therefore, in a flexible rate world it might be plausible to specify the exchange rate as a function of the relative interest rates, $e(r/r^*)$, where r^* is the interest rate in the foreign country. Denoting e' as the derivative of $e(r/r^*)$ we see that $e' > 0$.

Let us now perform the same comparative static experiment carried out above while recognizing that the exchange rate as well as agricultural production is now a function of the interest rate. Partial differentiation of (1) with respect to r and rearranging now obtains

$$(4) \quad \epsilon_r{}^p = - \frac{\epsilon_r{}^Z}{\epsilon_p{}^E + \epsilon_{p*}{}^{E*}} - \frac{\epsilon_r{}^e \epsilon_{p*}{}^E}{\epsilon_p{}^E + \epsilon_{p*}{}^{E*}}.$$

As we know from expression (2), the first term on the right-hand side of (4) is positive. However, since $e' > 0$ we can expect the second term on the right-hand side of (4) to be negative. Thus, the unambiguous result in (2) is replaced with an uncertain outcome. For the overall effect on prices to be positive it is necessary that $\epsilon_r{}^E + \epsilon_r{}^e \epsilon_{p*}{}^{E*} > 0$. We can expect there may be some instances when this inequality may not hold. Considering the effect on agricultural exports we obtain in elasticity form

$$(5) \qquad \frac{- \epsilon_{p*}{}^{E*}[\epsilon_r{}^S - \epsilon_r{}^e \epsilon_p{}^E]}{\epsilon_p{}^E - \epsilon_{p*}{}^{E*}},$$

which is negative under usual circumstances. Notice, however, that the overall decline in exports in (5) is larger than that found in (3). Thus, while quantity traded declines in both models, we perceive a tendency for the first model to underestimate the magnitude of the drop in exports associated with an increase in the interest rate. The reasons these results are obtained are quite simple and easily explained. As before, the initial effect, as far as the domestic agricultural sector is concerned, of a rise in the interest rate is to choke off domestic supply of the agricultural product which in turn tightens the supply situation in the international market. At the same time, however, the rise in the interest rate attracts investments to American shores thus forcing an appreciation of the now flexible exchange rate. While the tightening supply tends to drive the price of the agricultural commodity up, the appreciating exchange rate makes exports of the domestic country uniformly less attractive abroad. The decreased foreign demand for the commodity reinforces the downward export movement caused by the tightening of supply while it mitigates the original price rise caused by the shift in supply.

The important thing to note about (4) is not its ultimate sign, but that a relatively plausible generalization of even the simplest models recognizing the influence of monetary instruments on agricultural commodity trade makes it questionable what effects changes in monetary instruments have on agricultural trade patterns and agricultural prices. To appreciate the complexity of the problem at hand, one need only recall the extreme simplicity of the model involved and the fact that if it were to reflect adequately reality, the exchange rate would depend on agricultural trade flows as well as the level of the money supply and a galaxy of other variables that we have ignored.

If agricultural trade economists are to model accurately these phenomena, they must become much more acquainted with the operation of money markets. It is a curious phenomenon that most of the literature on agricultural trade (including the model above) takes a predominantly microeconomic, partial equilibrium approach. I do not mean to impugn the usefulness of partial equilibrium models. In many instances they are the most appropriate tool, but in others they have definite limitations which should be recognized. This is especially true when it comes to analyzing the impact of events that have their origin outside of the agricultural sector. Agricultural economists are not alone in their myopia. It is only relatively recently that writers on trade and asset markets have started to recognize the importance of agricultural phenomena for the overall economy in general (Van Duyne).

These comments suggest (or are meant to suggest) that an appropriate avenue of research in this area might include an extension of the research already started by Van Duyne. As I noted above, Van Duyne's analysis focuses on the effects of agriculture on the rest of the macroeconomy. It seems probable, however, that Van Duyne's model could be modified and extended to examine theoretically the impact of changes in asset markets on the agricultural economy.

The second major problem to be faced is the construction of empirical models, be they econometric or programming, that recognize the linkages between the agricultural trade sector and the money or financial part of our economy. A start, but only a start, has already been made in this direction by the studies of Chambers, Chambers and Just (1981), and Shei.

Researchers might follow the lead of empirical research in other areas of agricultural eco-

nomics that has been successful in introducing macroeconomic elements into agricultural models. The work of Penson, Penson and Hughes and Gardner (1976) serve as prominent examples. However, the first task that must be completed in this area is the identification of monetary variables that are likely to have an econometrically measurable effect on agricultural commodity trade. In the foregoing, we have already seen that several studies have been able to introduce the level of the money supply, the exchange rate, and the discount rate into agricultural trade models. However, there are likely to be many other essentially monetary factors or instruments which will have a dramatic impact on these markets. Before they can be included in structural models, they must be isolated. This area seems to be a particularly fertile ground for the use of causality tests of the type carried out by Barnett, Bessler, and Thompson.

Because it is always easier to suggest extensions of previous work than to pursue them, I have carried out some simple causality tests between several measures of agricultural commodity trade and several monetary instruments. These tests are rather quick and dirty and should be interpreted cautiously, but I feel that they provide some evidence on the relationship between monetary instruments and agricultural commodity trade. These tests rely on a somewhat arguable notion of causality developed and expounded in a series of articles by Granger and others (see especially Granger and Newbold) which suggests that causality requires a time delay. Thus, one time series is said to "cause" another if its past values somehow or other help to explain or lead current values of the other series. Rather than plunge into an extended discussion on the philosophical merits of this definition of causality, I refer you to a series of articles in the agricultural economics literature using this approach (Weaver, Bessler and Schrader).

My application follows that taken in the paper by Barnett, Bessler, and Thompson and boils down to simple regression techniques. If we have two time series $x(t)$ and $z(t)$ and the following regression equations,

$$(6) \quad x(t) = \sum_{i=1}^{m} a_i\, x(t-i) + e(t), \text{ and}$$

$$(7) \quad x(t) = \sum_{i=1}^{m} b_i\, x(t-i) + \sum_{i=1}^{p} c_i\, Z(t-i) + u(t),$$

where $e(t)$ and $u(t)$ are the stochastic components, $z(t)$ will be said to "cause" $x(t)$ if equation (7) provides a better description of the behavior of $x(t)$ than (6). As a practical matter the test of causality reduces to a test of the null hypothesis that $c_1 = c_2 = - \ldots = c_p = 0$ and can be based on the statistic

$$\frac{SSE_6 - SSE_7}{SSE_6} \, \frac{T - m - p}{p},$$

which is distributed as $F(p, T - m - p)$ where SSE_i is the sum of squared errors associated with equation i. To check for the existence of severe autocorrelation which might nullify the results of this test the Box-Pierce Q-statistic (see Granger and Newbold p. 93 or Bessler and Schrader) can be calculated and compared to tabulated chi-squared values.

Within this general framework, I carried out several separate investigations. I first tested the following four hypotheses: (*a*) the money supply does not "cause" agricultural exports; (*b*) the money supply does not "cause" agricultural imports; (*c*) the interest rate does not "cause" agricultural exports; and (*d*) the interest rate does not "cause" agricultural imports. As empirical measures of agricultural exports and imports I used value of agricultural exports and imports as reported in the *Survey of Current Business*. For the money supply I used currency in circulation, and for the interest rate I used the discount rate at the New York Federal Reserve. Data were monthly for the period 1973 through mid-1980 and $m = p = 12$. In both cases, there was no evidence of severe autocorrelation. The calculated F-statistics with (12, 56) degrees of freedom are, respectively: (*a*) 2.443, (*b*) 2.902, (*c*) 1.69, and (*d*) .9198. (*a*) and (*b*) are significant at the .05 level. Thus, there is some evidence for this time period of a causal relationship between money supply and agricultural exports and imports, with little evidence of a causal relationship between the interest rate and agricultural exports and imports.

From a somewhat more historical perspective, I next tested the null hypothesis that money supply did not "cause" the level of wheat exports for the period 1892–1952. Here the money supply is identified with the total currency in circulation in the United States. Data were annual and were obtained from *Historical Statistics of the United States*. The model used had $m = p = 5$. Again autocorrelation did not pose a serious problem and the calculated F-statistics with (5,50) degrees of freedom is 3.547 which is significant at the .1

but not at the .05 level. Thus there is some limited evidence of causality in this series as well.

One should be careful how these results are interpreted. A main reason for advising caution in this area is that there obviously exist several alternative measures of each of the aggregates under consideration. This is particularly true of the money supply variable. A glance at a recent issue of the *Survey of Current Business* reveals five separate definitions of the money supply ($M1 - A$, $M1 - B$, $M2$, $M3$, and L). Second, the approach used above leaves much to be desired, and a more attractive procedure for causal tests has recently been suggested by Ashley, Granger, and Schmalensee. However, the sort of test carried out above should remain attractive on a practical level in choosing variables to be included in larger-scale structural models.

The ultimate issue that one must face in any econometric or programming exercise is whether to build models specific to the problem at hand, as has been the case with the work of Chambers and Just (1981), or whether to aim at the construction of models that are sufficiently general to allow for a wide-ranging series of empirical examinations. The debate between big and small models is not new but is particularly relevant in this area because what is being suggested is the integration of two relatively disparate sectors of the economy in a single econometric or programming model. One must be particularly careful how this is accomplished since model specification ultimately determines the result of the modeling exercise. As a first step in this area, I would suggest the integration of reduced-form equations incorporating monetary instruments into fairly specific agricultural trade models. The literature on the specification of price transmission equations in econometric models of agricultural markets in developing countries that are isolated from the international market should be particularly helpful in this regard (e.g., Haessel and Vickery, Wong). Furthermore, because monetary instruments may often be classed as government controls, it seems that the work of Abbott on modeling governmental influences on international trade also would be particularly relevant.

I suggest the use of fairly specific models as a first step in this area because as a general principle it is necessary to know the enemy before he can be overcome. It seems better to first discover and solve the problems associated with smaller models and proceed from there to more complicated matters. One of the most valid criticisms of very large-scale general models is that, because of their very nature, they must ignore many details in their modeling effort. I feel that a more piecemeal approach would give modelers a better feel for just what can and cannot be ignored. On the other hand, large-scale models eventually will be indispensable to this area of research because it is only on a large scale that one can hope to capture all the market interactions and linkages which must be examined in such an area.

Interrelationships between Spot and Futures Markets: Some Implications of Rational Expectations: Discussion

James D. Sullivan

Grain markets in recent years have been highly volatile making price forecasting increasingly difficult. Price variability is a complex problem not only for producers but for processors as well. Commodity purchasing decisions involving when to be long, short, or on the market are increasingly important. Understanding the relationship between the spot (cash) and futures markets is one of the most important elements in an effective and efficient commodity purchasing department. To those firms in agribusiness, futures markets provide tools for risk management and pricing. Thus, information or knowledge about these tools is valuable to business operations.

Dewbre states the purpose of his paper is twofold: first, proposing an econometric model recognizing rational expectations and, second, exploring the implications of such an approach on two issues. The implications are directed toward *(a)* given changes in economic information, what is the direction and magnitude of cash and futures price changes along with the accompanying direction of causality; *(b)* the forecasting performance of the futures markets.

Unfortunately, the final version and empirical results were received shortly before the meeting. In these brief comments, much of the discussion will center on the practical application of the proposed model. In bridging the gap between the theoretical and applied, questions will be raised about the empirical model, the data, and the conclusions.

The Model and Data

I commend Dewbre in his research effort. He has recognized and outlined the inconsistency of the two market theories, i.e., supply of storage and anticipatory prices in explaining and predicting cash and future price relationships. The agribusiness community deals with this inconsistency every day in the applied economics arena. The proposed model which incorporates the rational expectation hypothesis does, thereby, provide the avenue for exploring these shortcomings.

In general, any model attempting to explain empirical price movements for a commodity must be based on assumptions not only about the structural relationships that determine the price but also those that determine the production, consumption, and inventory level of the commodity. The assumptions one makes about the equations are critical in determining the appropriate model structure. The theoretical specification of the stock demand equation does not include the farm price support loan, but was discovered to be the most significant variable. I would suggest for consideration a variable measuring the competitive demand of commodities on storage capacity. This could be expected price ratios as proxies for one commodity's storage demand relative to others. There is a point of confusion about the graphical solution as presented. The confusion rests with the future period price expectation variable during the iterative process. It appears that lagged values of the price expectation variable are being used. Will this lead to an accumulation of estimation error? Data transformation on the stock demand equation in the empirical model could have been included in the theoretical specification.

Data problems abound in empirical research. The exclusion of the price support loan variable illustrates this point. Necessary information, but excluded, to test Dewbre's proposed model is the estimated historical time period. We do know the frequency of the

James D. Sullivan is a corporate agricultural economist for General Foods Corporation, White Plains, New York.

period is monthly. It would be necessary for the proposed modeling approach to stand the test of time. The structure of the wheat market has changed. Wheat production and exports have grown considerably in recent years. A market participant's profile of rational expectations would be different in the 1960s than in the 1970s, particularly when one considers the importance of large export sales and changes in government policy reducing government stocks during the decade of the seventies. Other data questions: Why was the wheat market chosen for this investigative endeavor? Why the Kansas City market and not the Chicago market? How do we treat the various contract months?

The empirical results provide limited supportive evidence. Statistically, the results were satisfactory. However, no simulation or predictive results were presented. This is a necessary test for the proposed rational expectation approach. It was stated that over one-half of the turning points were picked up. I believe it is significant to know the circumstances surrounding those that were missed. An autocorrelation problem was admitted. The seriousness of this problem depends somewhat upon the pattern of estimation errors. Also, simulation results would have provided the necessary empirical evidence to support the graphical solution.

Dewbre's introduction of rational ecpectations in econometric modeling begins to close the gap left by the two well-known market theories. But, the paper does not provide sufficient evidence for me to accept the inferences drawn concerning the issues of direction, magnitude, and causality or that of the forecasting accuracy and performance of the futures markets. In both cases, he documents the conclusions drawn from prior research studies but fails to give enough supportive evidence, i.e., empirical results, to reach the conclusions drawn.

In closing, his paper does address the general theme of evolving relationships. I want to agree with inferences drawn with respect to direction, magnitude, and causality. However, I find that the analysis does not provide me with sufficient basis for complete acceptance. I do applaud Dewbre's effort. He has recognized and provided sufficient review of research to illustrate the shortcomings of the supply of storage and anticipatory price theories. The test of his approach lies with empirical and simulation results. I urge him to continue to pursue the matter and extend the analysis to other commodities.

Interrelationships between Monetary Instruments and Agricultural Commodity Trade: Discussion

Maury E. Bredahl

The evolving relationships of macroeconomic variables (which Chambers terms monetary instruments) necessitates two quite different types of analyses. The analysis of the evolving relationship of agricultural prices (and hence utilization, income, etc.) and macroeconomic variables in a post-harvest context (within marketing year) or across a few marketing years may be termed commodity analysis. The analysis of the evolving relationship of macroeconomic variables and the long-run equilibrium of the agricultural sector may be termed agricultural adjustment analysis.

Much of commodity analysis is logically directed toward the domestic and foreign demand sectors. The supply side of the livestock sector is also impacted by interest rate fluctuations in the short run. Much of this analysis utilizes a forecasting (versus projection) framework. This analysis identifies marketing strategies for farmers, procurement strategies for processing firms, and strategies for hedging in commodity and currency futures markets.

Agricultural adjustment analysis addresses the relationship of the long-run equilibrium in the agricultural sector (prices, comparative advantage, employment, for example) and macroeconomic variables. The results of this analysis might include a comparison of long-run adjustments to agricultural policies with flexible exchange rates versus fixed exchange rates, supply response to fluctuating (or high) interest rates, or changes in regional crop-livestock production in response to macroeconomic adjustments. This analysis requires a careful study of agricultural supply.

Consider the consumer demand for gasoline. In the short run, only the miles driven is a decision variable. In the long run, the replacement of the existing stock of cars (capital) with a more efficient fleet is the crucial factor. Forecasting gasoline consumption for the next six months (or even the next year) requires a much different analysis (model) than that required to project consumption for 1985 or 1990.

In my view, these two types of analysis of the evolving relationships in commodity markets are equally important and each deserves equal time. Chambers seems to address only the very important agricultural adjustment relationship. The remainder of this discussion presents my perspectives on (*a*) commodity analyses and macroeconomic variables, (*b*) agricultural adjustment, and (*c*) potential pitfalls of research on the interaction of macroeconomic variables and agricultural trade.

Commodity Analysis

A great deal may yet be learned from comparative static partial equilibrium trade models. Agricultural trade is characterized by numerous trade restrictions—many of a nontariff variety. It is characterized by state trading and large multinational grain firms. It is characterized by substitution among commodities (especially among feed grains, between feed grains and oilseeds, among vegetable oils, and between cotton and manmade fibers) in both the domestic and foreign markets.

Yet, much of the recent literature relies primarily on a free-trade, one-commodity model (Kost, Bredahl and Gallagher). A multicommodity model was presented by Chambers and Just but in a free-trade setting. Collins, Meyers, and Bredahl consider trade restrictions (via the price transmission elasticity) but in a single-commodity setting.

A logical progression of this type of analysis would seem to point to the development of theoretical multicommodity models that ex-

The author is an assistant professor, Department of Agricultural Economics, University of Missouri.

David Ervin and Leonardo Green are thanked for helpful comments.

plicitly consider trade restrictions. The impact of an exchange rate change may be much different in a restricted trade model than a free-trade model. For example, a devaluation of the dollar probably will reduce corn exports to the European Community (Bredahl et al.). On the other hand, oilseed exports would be expected to increase more than that suggested by a free-trade model. The internal corn price is fixed by the threshold price (and the variable levy) while soya prices would be reduced by a devaluation. Thus, soymeal would be substituted for corn in livestock rations.

I am less willing than Chambers to minimize the importance of the theoretical restrictions on structural and reduced-form elasticities derived from partial equilibrium models. The high correlation among economic time-series variables precludes, in many cases, the uncritical acceptance of econometric results. Theoretically derived restrictions play an important role in evaluating econometric results. For example, I have difficulty rationalizing a small, statistically nonsignificant, estimated coefficient on price with a large, statistically significant estimated coefficient on an exchange rate variable in export demand equations (Chambers and Just 1981).

Agricultural Adjustment

Although the long run is simply a series of short runs, quite different analysis (models) is (are) appropriate. The supply-side interaction with macroeconomic variables is most interesting. Important areas include capital formation, technical innovation and adoption, input costs, resource constraints, and labor migration. All of these variables are treated as exogenous in commodity analysis.

Chambers presents evidence of a causal relationship of monetary (macro) variables with agricultural exports and prices. This type of research is to be commended; the disconcerting gaps in our knowledge of these interactions should be closed. In addition to the caveats mentioned in interpreting Granger causality results, spurious correlation is assumed away; i.e., the apparent association between two variables occurs only because both variables are correlated with a third variable (Green and Albrecht).

A key question is the nature of the interaction between the agricultural sector and general economy. If the causality flows only from the general economy to the agriculture sector, agricultural models can be specified and estimated independently. If the interactions are simultaneous, the models must be estimated jointly. The causality evidence presented by Chambers seems to test only the unidirectional flow from the general economy to the agricultural sector. The test of simultaneous interaction of variables in the agricultural sector with those of the general economy variables is more interesting.

Given this emphasis, I am a bit puzzled by the direction of empirical research suggested by Chambers. The suggestion is "the integration of reduced-form equations which incorporate monetary instruments into fairly specific agricultural models." The testing of the interaction of the agricultural sector (particcularly agricultural exports) and macroeconomic variables (such as the interest and exchange rates) suggested by many agricultural economists (for example, Schuh, Tweeten) requires a much different emphasis. Many important questions—the impact of agricultural exports on the exchange rate, for example—cannot be answered by the approach suggested by Chambers.

Empirical Pitfalls

My empirical research has surfaced several factors that must be considered in research of the intraction of macroeconomic variables and the agricultural sector (trade). First, there is a clear distinction between commercial and noncommercial trade. The latter category includes PL480 and aid exports and trade by centrally planned economies. Commercial exports are clearly responsive to price (exchange rate) changes. Noncommercial exports would be expected to respond differently to price (exchange rate) changes or not at all.

Second, the impact of exchange and interest rates would be expected to vary among commodities. Trade restrictions are different for different commodities. An acceptable exchange rate measure specific to each of several commodities does not exist. The SDR-dollar ratio, which is heavily weighted by bilateral exchange rates of developed countries, is an unacceptable measure (except for soybeans and soymeal) because a large proportion of wheat and coarse grain exports are to developing countries. Price insulation policies also must be considered.

Third, cross-commodity effects are critically important. Substitution in both the

domestic and foreign demand sectors is well documented. Omission of these cross-effects leads to erroneous results and conclusions.

Fourth, estimated structural equations (and estimated reduced-form equations, for that matter) must be based on a sound theoretical model and recognize trade restrictions. I am continually mystified by the strong interaction hypothesized between wheat exports and the exchange rate. Consumer and producer prices in all developed countries and most developing countries are perfectly isolated from world market prices. Further, most income elasticities are small and, in some cases, negative. What is the mechanism, then, by which exchange rate variations impact significantly on U.S. wheat exports?

The Differential Impacts of Inflation on Southern Plains Farms by Selected Farm Characteristics

Francis X. O'Carroll

One important result of federal fiscal-monetary policy in recent years has been a general inflation so persistent that some observers fear that it may lead to a new structure of the national economy, perhaps with inflation as an inherent characteristic. Inflation is defined here as a continual increase in the average price level of goods and services. Serious questions arise concerning the impact of inflation on the farming industry. How will inflation affect ease of entry to the industry, and how will it affect the ability of farms of different characteristics to survive and expand? Do the traditional methods of farm financing continue to ensure survival of most types of farms at high levels of inflation? Would real growth of farm equity be enhanced by periodic indexing of the U.S. income tax schedules to the inflation rate?

The impact of inflation on the farming industry has been discussed by many authors from a general or aggregate perspective (Tweeten and Griffin, Ruttan, and Johnson, for example). The relationship between inflation and the farm sector's financial performance and structure, its financial markets and institutions, and farm level financial management, were recently surveyed, respectively, by Lins and Duncan; Klinefelter, Penson and Fraser; and by White and Musser.

Inflation impacts strongly on the main element involved in the expansion of the farm, namely land. Tweeten has shown that where inflation is fully anticipated, the cash cost of owning farm land is increased, while returns are partly deferred in the form of capital gains. Interest alone exceeds land earnings to produce negative cash flows; but, over time, the current returns increase to a point at which positive cash flow exists. In the purchase of land this phenomenon places the new entrant to farming at a competitive disadvantage relative to the established farmer who can use cash flow surplus from his existing holdings to offset the initial negative cash flow of a new purchase. The established farmer may also have a much greater advantage in the purchase of land if the mortgage interest rate that pertains to his existing holding was established before the present inflation was anticipated.

Inflation at high rates reduces the maximum size of farm that an entrant to farming may buy—directly because he can buy less land with a given equity, and indirectly because the diminished cash flow suffices only to support a smaller debt load. The case of a farm having zero cash flow in its first year was analyzed by Eginton, and is not considered in this study.

If land costs prove a barrier to entry in the farming industry, and if size and priority of establishment determine the potential for expansion, ease of entry to the industry and the national pattern of family farms will be seriously threatened. Entry, however, may still be feasible for limited resource beginners who have access to rental land and off-farm incomes.

Robison and Brake, applying capital budgeting techniques to long-term assets, have shown that the growth of the firm's equity will be reduced by inflation if lending limits are based on the income of the long-term assets.

Having indicated that a system of uniform loan repayments can contribute to the liquidity problem associated with inflation, Robison and Brake recommended use of a repayment system that more closely fitted the pattern of income under inflation.

Francis X. O'Carroll is a consultant in Stillwater, Oklahoma.
This work was partially funded by Hatch Project 1757 at Oklahoma State University.

This paper focuses on microeconomic effects of inflation, reporting the results of simulating the effect of inflation on Southern Plains farms which differ by such features as enterprise mix, size, tenure, and growth strategy.

Model Development

The following analysis was conducted based on typical farms in Oklahoma, Kansas, and Nebraska as described in U.S. Department of Agriculture's (USDA) *Typical Farm Data Series* (Fawcett and Thornton). The series provided estimates of farm size, labor requirements and wages, value and composition of machinery, and livestock complements. Land prices provided by the series were updated to represent a 1979 purchase price.

Envisioned in the base scenario for each farm was a young married farmer with a wife and two infant children—the full family, operating as a sole proprietorship, and having before him an expected working life of thirty years, during which it is his objective to maximize the amount of land owned subject to a level of leverage that has acceptable risk. A modest level of living, $12,600 per year in 1979 dollars, is assumed. In cases where a farm does not provide the farmer full-time employment (2,000 hours/year), off-farm work is assumed to be available at $7.50 per hour, approximately the national average industrial wage for males in 1979. The farmer's family is assumed to provide 600 hours of farm labor per year, and the farmer provides the remainder up to a total of 2,600 hours for the entire family. The children leave the farm in the twentieth year, thereby reducing total labor to 2,100 hours per year. As farm size increases the farmer increases his on-farm hours at the expense of the off-farm hours. Hired labor is used when labor in excess of that supplied by the family is required on the farm.

It was assumed that the farmer at the start of the thirty-year period had farming experience in which he acquired requisite skills and creditworthiness, and, if not inherited, the capital needed to begin operations in year one of the simulation.

The simulation model, a modified version of that reported by Eginton, is used to estimate the growth path of net worth of farms synthesized from the input data of the *Typical Farm Data Series* of the USDA. The model first calculates income components based on equity, labor, management, and if appropriate, off-farm work. Equity income is based on a 4% real rate of return (Tweeten). Cash flow is calculated by deducting U.S. income taxes, social security payments, and debt retirement payments from income. The decision as to whether to expand, and by how much, is then made. Cash flow generated in a given year is spent 1 January of the following year if expansion is allowed.

It is assumed that the owner's first use of purchasing power for expansion is to replace rented land by owned land. When all rented land is replaced, further expansion requires purchase of auxiliary resources, livestock, and machinery. The model specifies that all cash on hand be spent before the line of credit is tapped.

Two growth strategies, A and B_1 were used. Strategy A, the cash-flow strategy, permits purchase of resources for expansion if, subject to a preselected maximum farm leverage level, a minimum of 40 acres of land and auxiliary resources can be purchased with available internal financing and a line of credit based on current cash flow, if positive. The magnitude of the line of credit is cash flow times the amortization factor for the resources being purchased. The amortization factor used was the uniform series of payments present value (USPV), given the appropriate interest rate and the term for which the money was lent. It was required that purchase be made to the value of the cash on hand and the total line of credit.

Growth strategy B_1 was based on the "mining" of equity as collateral for external financing of growth. A leverage ratio of 1 limited the line of credit, and there was an added requirement for resource purchase, namely that cash flow be positive in the current year.

Loans for the purchase of land were extended for thirty years using a 3% real rate of interest, and a system of equal loan repayments was used. A 4% real rate of interest was used for short-term borrowing associated with purchase of machinery, livestock, and the covering of cash flow deficits.

The model handles inflation through provision for inflating resource earnings and prices and through adjusting real rates of interest to nominal rates. The model provides for indexing taxes to inflation on an annual basis or at other regular nonannual intervals. Money values for output variables are all reported in real

1979 dollars. Unless it is otherwise indicated, income tax schedules were indexed annually for inflation.

The benchmark farms served as a focus of comparison for the alternative scenarios used in the study. Key characteristics were initial size of operation, initial tenure, and growth strategy employed.

The initial size of operation measures the acreage of land farmed in year one. Three sizes were chosen; the two smaller, one-third and two-thirds the size of the typical or family farm size, represent the more common entry level farm sizes; the largest represents the established farmer or rare wealthy entrant to farming.

In the context of this study the terms full owner, owner, and full renter signify initial full, half, and zero equity in land, respectively.

The attributes of the benchmark farms for Oklahoma, Kansas, and Nebraska are (*a*) the intermediate size, that is two-thirds of the typical size, (*b*) the owner status as defined above, and (*c*) the use of growth strategy A. The initial sizes of operation for the Oklahoma, Kansas, and Nebraska farms were 640, 425, and 425 acres, respectively, and their respective net worths were $400,000, $310,000, and $561,000. Initially, all farms had 100% equity in livestock and machinery.

Results

First the effects of inflation rates on the growth of equity in the three benchmark farms under various growth strategies are presented (tables 1 and 2) and discussed. Then the effects under inflation of initial farm size, initial land equity rate, and size of off-farm income are presented. Third, the impact of tenure under inflation is examined. Finally, results are presented showing how farm growth is affected by such factors as unanticipated inflation, failure to index the U.S. income tax schedules for inflation, and automatic quinquennial indexing of U.S. income tax schedules for inflation.

Equity Growth Rates under Inflation

The pattern of equity growth rates under inflation was similar for all farms across all growth strategies used (table 1). The pattern shows that growth rates at all nonzero levels of inflation up to 12% are above those for no inflation and that they first trend upward to a maximum between 3% and 7% inflation and then trend slowly downward. Most net worth growth rates peaked at 6% or 7% inflation.

Data from table 2 provide insights into the behavior of the system underlying the growth rates pattern in table 1. The pattern of growth across inflation rates reflects the influence of factors such as (*a*) the growth strategy used, (*b*) the nonlinearity of the U.S. income tax schedules, and (*c*) the use of uniform loan repayments schedules.

With higher inflation, the greater interest rates reduce income initially, causing negative cash flows, thereby restraining growth in period one, the first fifteen years. Subsequent

[a] See footnotes, table 1, for details of the Oklahoma farm and the growth strategies. Strategy B is similar to strategy B_1, except that expansion is not restrained by the positive cash flow requirement of strategy B_1. Dollar values are comparable, being 1979 dollars.
[b] Number identified by "b" are thirty-year averages.
[c] Data pertain to period 1, the first 15 years.
[d] Net worth for years 1 and 30 are, respectively, as of 1 January and 31 December. The average net worth is that for end of year.

recovery leads to stronger growth in the second period. For example, under strategy A, at 12% inflation, period one growth rate of net worth is 4.40%; but for the overall period it is 4.46%. Similar results are obtained for strategy B_1, but the magnitude of growth rates reflects the generosity of the line of credit associated with the strategy.

In the absence of inflation, growth rates of net worth were lowest. With strategy A, all of the acreage expansion occurred in the first period (table 2). Data not shown revealed that all of the purchases of 600 acres of land were made by year eight, and thereafter no purchases occurred. The reason is that cash flow, which with low interest rates was large in the first year, thereafter declined continually so that negative cash flows averaging $4,900 occurred throughout the second fifteen-year period. The system of uniform loan repayments and high taxes contributed to this outcome. In the absence of purchases for expansion, interest payments declined annually at an increasing rate, and principal payments increased by an identical amount. Taxable income increased as interest payments declined, and taxes increased disproportionately because of increasing marginal rates. Taxes and principal payment increases far exceeded the increase in income annually and the result was an ever-declining cash flow.

Great increases in farm size were achieved under strategies B_1 at 6% and 12% inflation. The results show that by operating under fairly restrictive leverage ratios growth can be considerable if lenders are willing to provide short-term financing for cash-flow deficits.

The Impact of Initial Size of Operation on Growth of Equity, Given Inflation

The results for the three sizes of farm under two levels of inflation (scenarios 1 to 6), table 3, show that the large farm grew faster than the medium-sized farm, (4.87% vs. 4.72% at 6% inflation, for example). However, the growth rate of the small farm was greatest of the three at 12% inflation and greater than that of the medium-sized farm at 6% inflation. The relative success of the small farm in growth rate (but not absolute growth) is attributed to the strong influence of off-farm income in the first period of fifteen years, where the growth rate was much higher than for the overall period. The greater growth of the large farm is attributed to the greater initial net worth and size which made more income available for growth. Scenarios 7 and 8, compared to 5 and 6, show that with the same initial size of operation at both levels of inflation, the farm with the smaller net worth makes smaller absolute increases in net worth. However, the rates of growth do not always correlate with initial size of net worth. Scenarios 9 and 10 compared to scenarios 6 through 8 show that a high off-farm wage ($15.00 vs. $7.50) can go a long way toward boosting the expansion of farm size. Growth rates were increased by about one percentage point. It must be noted that off-farm income here, through its contribution to growth in early years, causes itself to be phased out. An owner with a high off-farm wage could opt to hire farm labor to service his farm growth and continue to work off-farm with dramatic effect on his farm growth rate.

In synthesizing the small farm from the typical farm, no downward adjustment of rates of return was made to reflect possible losses in operational efficiency. If such adjustments were made, it is likely that increases in net worth would have been modest.

The Impact of Tenure on Growth of Equity

The full renter grew at a faster rate than the full owner, but the full owner added substantially greater equity to his farm in thirty years. Having only 640 acres to farm, the renter benefitted from off-farm income to the extent of $5,700 per year on an average (table 4). An increase in size of operation would help the initial renter, but he would lose some of the benefits of off-farm income; therefore the high rate of growth could not be maintained. Note that year 1 results are the same irrespective of the inflation level in both main tenure situations—because assets are held at full equity in year one by both full owner and the renter. Data for the owner is included for contrast. The very modest increase in net worth (in thousands of dollars) for initial renter, 266, is dwarfed by that for the full owner, 2365. In year thirty, the renter still had smaller equity in real terms than had the owner in year one. Land ownership in farming is seen to be the primary criterion for success. By reducing initial land ownership through smaller mortgage that can be serviced with cash flow, higher inflation rates give a comparative advantage in farm growth to high-equity or established owners at the expense of the low equity and entry level farmer.

Table 3. Results for the Oklahoma Farm Showing the Growth Impact of Initial Size of Operation, Initial Land Equity Percentage, and Off-Farm Wage Level, at Two Inflation Rates (Growth Strategy A)

[a] See footnotes, table 1, for details of the Oklahoma farm and the Growth Strategy A.
[b] Numbers identified by "b" are 30-year averages.
[c] For full owner and full renter year 1 data at 6% inflation are the same as those at 12% inflation because there is no debt in either tenure situation in the first year.

Inflation, Taxation and Interest Rates

Expectations by the electorate that high inflation will persist could result in Congress being pressured to index taxes to inflation. The absence of tax indexing produced the lowest growth rate of the Oklahoma benchmark farm, 4.19% (table 5). Indexing taxes every five years was nearly as beneficial to growth as indexing annually, and annual average income tax paid increased by only $200. Both instances of tax indexing increased growth rates by about one-half a percentage point above the nonindexing result.

Failure to anticipate inflation by the lender who financed the original land purchase, resulting in a 3% nominal instead of a 9% nominal interest rate, would prove beneficial to the owner of the Oklahoma farm. The growth rate increased by 1.24 percentage points, based on a loan on 320 acres at 1979 prices, fully leveraged.

Finally, the no-tax scenario is included, not because it is realistic or likely, but to show the magnitude of the impact of the tax burden at 6% inflation. It accounts for 0.4 percentage points difference from the indexed taxes result. That small change reflects the low annual average tax burden experienced at 6% inflation by a farm which has substantial deductions to keep taxable income low.

Summary

The growth rates of net worth under inflation first trended upward and then trended downward slightly. The peak growth rates were reached between 3% and 7% inflation; most, however, peaked at 6% or 7% inflation. The proportional impact on net worth growth rate from 6% to 12% inflation was uniform across farms of widely differing characteristics. At highest inflation rates, however, the growth rate of equity tended to decline. Moreover, at inflation rates above 6% cash flow deficits were common. Although leverage ratios were low, the magnitude and frequency of cash flow deficits were such that lenders who have not yet fully accepted the permanence of capital gains equity would probably be reluctant to offer refinancing.

If a family farm structure is consistent with rapid expansion to an economic size unit in early years and restrained growth in later years, results of this study indicate that low inflation rates contribute to such a structure. Furthermore, low inflation rates allow an entry level operator with a given equity, management, and labor reserves to purchase a large farming unit. Low inflation rates also allowed farmers with a given equity to get off to a faster start, using cash flow surpluses to purchase more land. With time, uniform annual payments on mortgages having an increasing component of principal payment, raised taxes and reduced disposable income for expansion. The situation could be different if a given equity would have been used initially to finance purchase of as large a farm as possible subject to equity and cash flow restraints.

Initial equity was a major factor determining the absolute growth in farm size, with full owners growing far more than renters beginning with the same acreage. The implication is that if society wishes to restrain growth of farms, estate taxes can play a major role by reducing equity passed to heirs who enter farming. Such a policy would need to be accompanied by policies such as higher property tax rates for nonoperator owners to discourage investment in farmland by nonfarmers.

These results depend heavily on the assumptions which included availability of off-

Table 5. Inflation, Taxes, and Interest Rates Results for the Oklahoma Benchmark Farm, Using Strategy A

	Growth Rate	Net Worth Year 30	Acres Owned Year 30	Income Taxes Mean	Cash Flow Mean
	(%)	($1,000)	(Acres)	($1,000)	($1,000)
Taxes not indexed	4.19	1,372	1,600	6.5	4.8
Taxes indexed, 5-year	4.70	1,586	2,040	2.7	6.8
Taxes, indexed annually	4.72	1,598	2,080	2.5	7.2
Low interest rate[a]	5.96	2,273	3,120	3.0	11.6
No taxes	5.12	1,792	2,440	0.0	8.6

Note: See footnotes, table 1, for details of the Oklahoma benchwork farm and of growth strategy A. An inflation rate of 65% was used in the low interest rate case (inflation not anticipated).

[a] An interest rate of 3% nominal was used (even though 6% inflation existed) on the mortgage for the original purchase. The mortgage represented the value of 320 acres at the 1979 price.

farm employment, deterministic growth not subject to shocks which could cause illiquidity, full anticipation of inflation, a constant low real level of consumption, and uniform debt payment schedules. The model, which currently provides fairly crude approximations of long-term results using a parametric approach, does so at a very low cost. It could, however, be made much more sensitive and realistic by including elements to make explicit adjustments with respect to many of the assumptions listed above and with respect to a number of assumptions implicit in the model. Future studies will include a more detailed modeling of the mechanisms through which inflation is incorporated in agriculture, a more conventional consumption function, stochastic income elements, and loan repayment schedules other than the equal loan repayment schedule currently used.

Changing Agricultural Prices and Their Impact on Food Prices under Inflation

R. C. Kite and J. M. Roop

We know that mankind has lived with, suffered the consequences, or reaped the benefits of inflation since records have been kept. Despite the centuries of experience and hours of study and debate, we still are far from understanding how to deal with persistent inflation and, in many cases, cannot agree among ourselves as to when or where its influences are beneficial or burdensome.

From our particular orientation and training, it is difficult for us to address the issues of inflation in anything but a microeconomic perspective. Yet at the microeconomic level, there is no inflation, just price change. So before we begin, let us look a little closer at inflation. There is far less agreement, we find, on a definition of inflation than there is on the consequences of price increases. We sketch out this process by way of introducing the empirical work we report later in this paper. This process reveals that microeconomic price increases in one sector, through their initial effect on consumer demand and their direct and indirect effects on costs of intermediate materials in other industries, can lead to inflation in the macroeconomic sense. Because this process is so fundamental to the way we measure the effects of inflation, it is worth looking at it in somewhat more detail.

To use a common economists' device, assume that oil prices rise worldwide, with domestic prices rising in lockstep. The immediate effect will be on consumption. With energy prices higher, substitution will occur—less energy (gasoline, home heating oil, etc.) will be consumed relative to other commodities. Simultaneously, higher energy costs as factors of production or intermediate materials will permeate the industrial structure of the economy. With higher relative energy prices, firms will substitute capital and labor for energy until, at the margin, relative prices are equated to relative marginal products. This will raise costs to all users of energy in rough proportion to their energy use, with consequent increases in product prices. Increases in product prices will, likewise, stimulate increases in negotiated wages as workers attempt to retain their prior relative standard of living. Higher wages and higher product prices will cause other changes in consumption. Clearly, this process, to the extent that it persists, is what we call inflation.[1]

There are several aspects of this process that we can highlight: (*a*) one consequence of price changes is a change in consumption patterns; (*b*) changes in costs will alter production arrangements in other industries, not just that industry immediately affected by price changes;[2] and (*c*) "second-round" effects will wash through the entire economy, including the industry initially affected. All of these are microeconomic effects of inflation. But the task of measuring them requires a macroeconomic perspective.

Even the concept of inflation is macroeconomic. Consider the definition of Prentice and Schertz (p. 1): "Inflation, a rise in the general price level, represents a decline in the real purchasing power of money." The terms "general price level" and "purchasing power of money" are macroeconomic, not microeconomic in nature. Johnson's (p. 104) definition, while very similar—"a sustained

R. C. Kite is Director, Agricultural Economics Research, Merrill Lynch Economics, New York. J. M. Roop is a senior research economist, Battelle—Pacific Northwest Laboratories, in Richland, Washington.

[1] We chose this particular commodity to illustrate that inflation may well be a consequence of normal economic activity, in contrast to the undertone in much of what is written that suggests that inflation is somehow imposed on the system. Continuous depletion of a nonrenewable resource can certainly lead to persistent price increases, and to increases in the general price level if the resource has limited substitutes. This analysis is further predicated on the reasonable empirical assumption that the Federal Reserve System, whether using interest rates or monetary aggregates as intermediate targets, cannot effectively prevent such price changes from affecting the general price level.

[2] The effects of uncertainty on the decision making of the firm is another consequence of inflation, quite apart from the adjustments required by changing relative prices.

rise in prices"—has the added advantage of simplicity. But Johnson recognizes that "one encounters problems of some difficulty as soon as one tries to apply it in practice." The three major difficulties are (*a*) some price increases are not inflationary; (*b*) the choice of which prices or indexes are to be used; and (*c*) most measures of price do not adequately reflect quality changes. Another definition, attributable to Pigou (p. 14), finds inflation to exist when "money-income is expanding relative to the output of work by productive agents for which it is the payment." This attention to income flows or factor returns is the complement to price changes in commodity markets; it stresses the general equilibrium, or microeconomic, aspects of inflation.

This paper will address some inflationary effects—we concentrate on measurement rather than attribution. Since we are dealing with microeconomic measurement, by which we mean measurement of specific elements such as the number of beef cows on farms, we will avoid much of the argument about cause. Instead, we focus on price changes and the consequences of these changes.

This, then, is what interests us here: the adjustments that are made necessary by price increases and how these adjustments influence food and agriculture. We gauge these adjustments by simulating the microeconomic activity in the agricultural sector with the Merrill-Lynch Agricultural Model. This simulation provides prices, quantities, and markups for the major outputs of the agricultural sector. These are then used to examine the macroeconomic consequences of changes in the agricultural sector using the Battelle FORSYS (Forecasting System) macroeconomic model. The results of these simulations are reported in the fourth section of this paper. Sections II and III provide descriptions of the agricultural and macroeconomic models, respectively.

The Merrill-Lynch Agricultural Model

The Merrill-Lynch agricultural model is a quarterly microeconomic model of major agricultural commodities. The crop portion of the model is a disequilibrium submodel, allowing for partial price adjustment when current and desired stocks are not in equilibrium. The livestock submodel is an equilibrium model that uses the U.S. Department of Agriculture supply-utilization accounting framework.

The livestock submodel has markets for beef cattle, calves, hogs, broilers, turkeys, eggs, and milk. Price determination occurs at the wholesale market, with marketing and processing costs added to obtain the retail price. Farm price is determined from the wholesale market price by taking into account transportation and other costs.

The crop submodel has markets for food grains (three wheat commodities and rice), feed grains (corn, oats, barley, and sorghum grain), oil crops (soybeans, peanuts), and cotton. Production is determined from yields and acreages, with utilization demands and desired stock positions determining the current market price at the wholesale level. Equilibrium price at the farm level and cost of production then determine acreage planted with crops competing for alternative uses of land.

Farm income is based on production and farm level prices for cash receipts and input costs and cost of production for expenses. The CPI for food and beverages is derived from producer level prices for agricultural commodities and markups that result from additional processing and retailing.

The major exogenous inputs to the agricultural model are disposable per capita income, interest rates, population, the CPI for all items less food and beverages, and major wholesale prices that constitute costs of agricultural production—fertilizer, fuels and natural gas prices, and machinery costs. Wage rates and transportation costs are used to determine the marketing and processing costs that get added to determine retail prices. The major program variables that enter are loan rates, farm-held reserves, target prices, and other support program variables. Set-asides and acreage diversions are also included in determination of acreage planted.

Some of these exogenous variables are determined in satellite models run prior to a solution for the agricultural model. The two major agricultural satellite models are the fertilizer model and the farm machinery model.

Battelle's FORSYS Macroeconomic Model

Battelle's FORSYS (Forecasting System) macroeconomic model is a 112-sector, annual, dynamic, input-output model of the U.S. economy. Final demand consists of consumption detail by fifty-nine categories, investment detailed by eighty categories of producers

durable equipment, and twenty-seven construction categories, government expenditures, and net exports. Gross output is determined from these final demands and the input-output structure of the economy. Prices and wages are determined by sector within the model and are used to determine net incomes to business and consumers. Relative prices and incomes are determinants of consumption and investment decisions. Interest rates are determined endogenously in a monetary sector that relies on major monetary flows among agents of the economy to determine effective prices. We look briefly at each of these sectors, then describe how information from the agricultural sector model is introduced into the FORSYS model. We touch but lightly on all sectors except consumption, which plays a prominent role in our results.

The solution process for the FORSYS model begins with an initial estimate of prices and income used to compute consumer demand by product. Prices for the fifty-nine categories of consumption are obtained by conversion of the supply prices by input-output sector. For example, a dollar spent on personal consumption category titled "semidurable household furnishing" may be distributed to a number of FORSYS manufacturing industries, as well as transportation and trade margins. Thus the price for semidurable household furnishing is constructed as a fixed-weight aggregation of the market prices for these same sectors. With prices by consumer good and total expenditures, a simultaneous system of demand functions is employed to predict expenditures by fifty-nine categories of consumption. These consumption estimates are derived from a two-step decision process, with consumers first allocating their budget among nine broad categories: food, fuel, clothing and footwear, household operations, household durables, private transportation, health services, and other services and nondurables. After expenditures on each of these aggregate groups is determined, the model then allocates expenditures among the subcategories within each group. This system of equations is based on the indirect transcendental logarithmic utility function, which allows for both substitution and complementarity among consumption commodities, both within and between the broad categories.

FORSYS next determines the other elements of final demand and output: exports, imports, government expenditures, inventory change, fixed investment, and gross output. With current estimates of output and capital stock (derived from investment and past capital stock), a "desired" level of employment for the current year is obtained. This and previous employment determine current employment. Unit labor costs, based on wage rates and labor requirements, are then one of the major explanatory variables in the determination of prices.

Domestic prices in the FORSYS model follow the price "dual" formulation of input-output theory. Material costs are passed through on a dollar-for-dollar basis, while factor returns, making up value added, are treated separately. Supply price is then determined as a weighted average of prices of these domestically produced commodities and imported commodities.

The FORSYS model then ties this information together by estimating various income components of aggregate income, calculating the required national income and product accounts, estimating the domestic saving rate and hence determining consumer expenditures, which feed back into the demand system. We need further explain only how agricultural forecasts from the agricultural sector model feed into FORSYS.

FORSYS contains seven consumption sectors and five input-output sectors that tie in directly to the agricultural sector model. The consumption categories, meat and dairy products, poultry and eggs, fruit and vegetables, fats and oils, bread and cereal products, purchased meals and beverages, and tobacco products, tie in directly with the categories in the agricultural sector model that relate to consumer prices. Quantity and price for the five input-output sectors can be built up from the commodity detail of the agricultural sector model. Of these five sectors—dairy and poultry products, meat animals and livestock, cotton, food and feed grains, and other agricultural products—all but the last are determined endogenously. Two other input-output categories, meat and dairy processing and other food processing, are available to satisfy final demand for food consumption.

We modify our macroeconomic forecasts by first altering the domestic agricultural price for commodities. This modification then influences the PCE deflators with consequent adjustment in consumption. Shifts in final demand then change the composition of output, and ultimately alter income and relative

prices. The model is in equilibrium when the adjustments are complete.

Simulations with the Models

Our empirical results consist of four impact analyses of the agricultural model with one impact analysis of the macroeconomic model. For our baseline we simulate both the agricultural and macroeconomic models beginning in 1977. Our results are then reported as deviations from this baseline. The three extreme agricultural simulations examine (*a*) the effect of eliminating the farm-held reserve; (*b*) the impact of a 10% increase in the CPI for all commodities less food and beverages; and (*c*) the effect of raising income 1% for each of five years. A less extreme simulation increases both prices and income. The price changes that result from the second simulation of the agricultural model are then used to simulate the macroeconomic model, measuring the consequences of the agricultural sector changes on the macroeconomy.

Agricultural Model Simulations

Our first simulation is designed to gauge the impact of support programs on agricultural commodity prices. We proceed from the belief that inflation is transmitted to agriculture via dependence on inputs that originate off-farm. We then examine how these changes are retransmitted to the general economy via changes in raw material prices and through taxes drawn to support agricultural commodities.

The agricultural support mechanism is, in fact, one of the ways in which general inflation is institutionalized into the agricultural economy. It also serves to spread some of the risk inherent in agriculture across a wider base. Since the primary "damage" done by inflation at the microlevel is to increase risk, the support mechanism serves to reduce some of the detrimental impact of inflation. We cannot, however, argue that the net effect has contributed to the efficient use of resources: this will occur only if the support rates have been established from accurately anticipated changes in relative prices—a most unlikely event. The cost of these supports is inefficiently organized resources if they do not reflect market relative prices.

Consistent increases in corn production costs have been translated into the corn loan rate, and the loan rate, in turn, has provided a lower limit to prices. The question, then, is what influence has this had on food and agriculture?

The first agricultural model simulation suggests that, so far as the American consumer is concerned, the absence of farm-held reserves would have made very little difference in the near term. Food prices would have been only slightly lower for the first year. Prices received by farmers for crops would have been lower initially, but livestock prices would have increased. Table 1 shows the changes in cash receipts, prices received, and the CPI for all food.

The data in table 1 show about a $1 billion net negative impact on cash receipts for the first two years, but a net increase of $20 billion for the second two years. These results, at least partially, reflect the short crops of 1980 and the transfer of supplies from the first two years to the latter two years, via the grain reserve. We do not propose that these results reflect the impact of more or less inflation; rather, they indicate that attempts to spread the risk (to achieve stable farm incomes or food supplies) must result in both costs and benefits. In the special case shown here, the maintenance of farm-held reserves causes producers of crops to benefit through stable short-term income, but livestock producers to lose. Higher feed costs would discourage increased meat production and, although food prices decline initially, reduced meat production will mean higher prices later.

Table 1. Impact of Eliminating Farm-Held Reserve—Cash Receipts and Prices 1978 to 1981

	Year			
	2	3	4	5
	---- (Change) ----			
Prices received[a] (%)				
Crops	−3.3	−1.1	4.2	4.5
Livestock	.8	6.3	8.2	6.1
Cash receipts ($ bill.)				
Crops	−1.1	3.4	2.3	5.9
Livestock	.3	3.3	6.4	6.0
CPI—all food[a] (%)	0	.4	1.2	1.1
Beef cattle on farms[a] (mill.)	.1	.2	1.0	1.9
Breeding sows[a] (mill.)	.1	.5	1.0	1.2

[a] Fourth quarter.

This simulation illustrates two important points. First, market intervention in the form of support programs has a differential impact on agricultural producers, with dynamic consequences that are difficult to anticipate. Second, support programs institutionalize a higher cost structure.

It is through this higher cost structure that evidence is gained to support the proposition that inflation is good for (or at least not harmful to) agriculture. We would take issue with this argument unless it is made conditional on higher costs institutionalized by support programs. Gardner, for example, concluded that a 1% change in the CPI would result in a $950 million increase in real net farm income. Tweeten and Griffin report that prices paid by farmers will respond (long-term) one-to-one with general inflation and found no significant relationship between general inflation and prices received.

Our second simulation provides some evidence regarding inflation and agriculture. We find that an increase in the overall CPI does have an influence, but primarily through reduced real consumer incomes. A 10% increase in the nonfood component of the CPI gives us an initial 5% reduction in crop prices, 10% reduction in livestock prices, and about a 9% drop in total cash receipts (table 2). These results occur since, with nominal income held constant, the increase in the CPI reduces income enough to disturb significantly food consumption patterns. We emphasize that this simulation represents an extreme case, but we use these extremes to bracket our results.

So, our third simulation looks at another extreme. When real income is elevated by 1% for five years, we obtain results much like those of Gardner. At the end of five years, cash receipts are $1.8 billion higher, with a mid-period average of slightly over $900 million. Because production expenses have been held constant, this also represents the change in net income. Our final simulation tries to find a set of assumptions intermediate between these extremes; we balance increases in both the nonfood CPI and income increases with less dramatic results. Cash receipts are marginally lower and net income is also lower because of the production cost pass-through observed by Tweeten.

We conclude, then, that inflation is not harmful to agriculture only when it is validated by government support programs. Without this validation, our findings suggest that a 1% increase in inflation will reduce farm prices and income by approximately 2%.

Table 2. Percentage Change in Prices Received and Cash Receipts Resulting from a 10% Increase in Nonfood Components of the CPI

	Years				
	1	2	3	4	5
Price received					
Crops	−5.3	−8.8	−8.9	−7.0	−4.9
Livestock	−10.0	−8.0	−4.0	−1.0	−1.0
Cash receipts					
Crops	−7.5	−11.0	−12.0	−10.0	−7.5
Livestock	−11.0	−10.0	−6.0	−2.0	−2.0

Simulations with the Macroeconomic Model

To validate that the consequent effects of the initial price changes represented by the second agricultural simulation would have no devastating effects on the initial macroeconomic simulation, we resimulated the macroeconomic model for a 10% reduction in livestock prices and a 7% reduction in crop prices. The simulation affirmed our major concern about the effects of agricultural price changes on real income, that the effects were negligible. So the agricultural sector simulations are uneffected in any major way by processing these changes through the macroeconomic model.

Of more interest to this paper is the impact of these price changes to the consumption pattern of consumers and the supply prices of the nonagriculture sectors of the economy. We highlight these results in table 3.

Conclusion

Persistent price changes outside of agriculture bring about changes in the cost of production. All other things being equal, farm income will decline. Thus, if we measure the well-being of the farm sector in terms of real farm income, abstract from the effects of inflation on land values and ignore the uncertainty effects of inflation on production, then we conclude that inflation has a substantial negative effect on the income position of agriculture. But all

Table 3. Macroeconomic Changes from Agricultural Price Reductions, First-Year Effects

	Level	Percent Change
GNP (bill. $1972)	+.7	0.05
PCE (mill. $1972)	+452	0.05
National income (bill. $)	−5.6	−0.46
Disposable income (bill. $)	−7.0	−0.55
Food consumption ($ mill.)		
Meat and dairy	733	1.4
Poultry and eggs	500	3.4
Fruits and vegetables	215	0.8
Fats and oils	266	5.9
Bread and cereal	33	0.2
Purchased meals	−364	−0.6
Agricultural investment (mill. $1972)	$ 79.6	0.6
Gross agricultural output (mill. $1972)	$983.4	0.8
Implicit deflators (1972 = 100)		
Gross national product	−0.7	−0.5
Personal consumption expenditures	−0.8	−0.6
Livestock products	−6.9	−4.7
Fruits and vegetables	−4.0	−2.6
Fats and oils	−3.9	−2.6
Bread and cereals	−2.9	−2.0
Purchased meals	−1.9	−1.3

Note: Livestock and product prices reduced 10%; other food products reduced 7%.

other things are rarely the same. The observation that inflation has little or no harmful effect on the farm economy we attribute to two compounding influences: first, government support programs have institutionalized higher costs, thus mediating the effects of inflation; second, coincident inflation and rising real income make it difficult to identify the separate effects of these two, allowing the erroneous conclusion that inflation does no harm to agriculture.

Microeconomic Impacts of Inflation on the Food and Agriculture Sector: Discussion

Vernon R. Eidman

The O'Carroll paper addresses several inflationary impacts on farm firms. I will start by critiquing the issues addressed and then turn to a discussion of additional work that might be beneficial.

The first set of results suggests that the real growth rate of equity reaches a maximum as inflation reaches 3% to 7% and then declines for higher rates of inflation. The rates of growth are somewhat greater when a higher leverage ratio is used, but the peak occurs in the same inflation rate range. The author indicates the reduction in growth at higher inflation rates occurs because the greater interest rates reduce income in the earlier years, causing negative cash flows during the first fifteen years. However, the rather surprising result (of lower real rates of growth with inflation rates above 3% to 7%) appears to be caused in large part by the zero real rate of growth assumed for land values. Including a real growth rate of 3% to 4% for land values (which recent studies such as Melichar's would tend to support) would result both in larger equity gains and increased borrowing possibilities. Through the compounding effect, the addition of real rates of growth in land values would increase the cash flow each period, with the amount of the increase being greater for higher rates of inflation. Thus it cannot be argued that this effect would be uniform for all rates of inflation. The sensitivity of the model to this factor should be considered before concluding that real rates of equity growth decline as inflation rates move above 3% to 7%.

The second section considers the effect of alternative farm sizes under two levels of inflation. The relatively favorable showing of the small farm is largely dependent on the availability of off-farm work and the manner in which the annual net cash flow is calculated (which I comment on below). Further, the author notes that a high off-farm wage could have a dramatic effect on the farmer's growth rate—not a surprising result.

The results for alternative tenure situations suggest that the full-renter grew at a faster rate, but that the full-owner added considerably more equity to his farm in thirty years. Inclusion of a positive real rate of growth in real estate values (as noted above) would enable the full-owner both to grow at a faster rate and to add to equity more rapidly than the O'Carroll results indicate. This would make the full-tenant less competitive relative to the full-owner.

Perhaps the most interesting result is the estimated impact of indexing taxes to inflation every year, every five years, and no indexing. The author indicates indexing taxes every five years rather than every year yields approximately the same rate of growth in equity—a rate approximately 0.5% greater than with no indexing over the thirty years.

The summary indicates that similar results were obtained on farms of widely differing characteristics. However, all of the farms have a similar crop-livestock mix and all have a substantial amount of net worth at the start of year one. The method of calculating the annual net cash flow, the manner of including off-farm employment and the assumption on family living further restrict the range of situations analyzed.

The Oklahoma, Kansas, and Nebraska farms considered are primarily crop farms with relatively minor livestock operations. Neither intensive livestock farms nor crop farms in other regions were considered. The lowest equity situation considered was a renter on a 640-acre Oklahoma farm with an initial net worth of $71,000, who owned the machinery and livestock debt-free. Each of the other farms had a starting net worth of at least $200 000. Farms with initial low net

Vernon R. Eidman is a professor of agricultural and applied economics, University of Minnesota.

University of Minnesota Agricultural Experiment Station Scientific Journal Series Paper No. 11859.

worth and poor debt-equity ratios were not considered.

The method of calculating the net cash flow further reduces the distinction between alternative farming situations. Net cash flows were calculated as 4% of the owned land value, plus a fixed return per hour of operator and family labor, plus the operator-management return (calculated as a fixed percentage of cash receipts), plus a fixed return per dollar for investments in machinery, plus a fixed wage per hour for off-farm work, minus a fixed family living expense, minus mortgage payments, minus federal income tax, minus the social security tax. The use of a fixed rate of return to land, labor, capital, and management resources minimizes the differences in level and pattern of net cash flows that exist between farms of different types and sizes.

The assumptions concerning the availability of off-farm employment and family living requirements are the same for all farms, another reason for similar growth rates across alternative farms. In each case, off-farm employment was considered to be available at $7.50 per hour for operator labor not required by the farming operation, regardless of the season of availability. Furthermore, consumption for the family of four was assumed to be a constant $12,600 in 1979 dollars. Both the low and constant real consumption level as the family's age and financial situation changes appears unrealistic. For these reasons it is difficult to agree either that a wide range of firms was considered or that the results obtained are indicative of the firms analyzed.

Perhaps a somewhat different approach to estimate the differential impacts of inflation on alternative sizes and types of farms would be more fruitful. A given rate of inflation as commonly measured can arise in a variety of ways, with each of these ways resulting in a somewhat different set of farm level input and product prices. This makes it difficult to select one combination of input and product price changes to consider in a firm level model for a given rate of inflation. However, Kite and Roop's paper suggests a way out of this dilemma.

Alternative combinations of inflationary forces could be selected and macroeconomic models of the economy used to trace the impact of the forces on the price of inputs farmers purchase and the demand for agricultural products. The equilibrium product prices at the farm level could be calculated with a model of the major crop and livestock sectors. The resulting input and product prices could be used in firm-level simulation model to test the impact of inflation on farm firm growth.

The farm simulator would need to be more detailed than the O'Carroll model. To serve as a useful experimental device, the firm simulator must include a sufficient level of detail to trace the impact of price changes and the resulting operator's decisions on the finanability of returns to productive assets. The ple, the inclusion of alternative production systems (reflecting alternative labor-capital combinations that can be used to produce a product) for each alternative product is important for two reasons. The optimal system may change as the firm's equity position improves, and the optimal production methods and product combination may change as inflation affects relative price ratios. Including the stochastic nature of production may be important in areas of high yield variability because of its effect both on net cash flows and the leverage ratios that can be sustained. One of the characteristics commonly associated with inflationary periods is increased uncertainty of input and product prices, indicating such variability should be considered in the model to assess the effect of inflation on rates and variability of returns of productive assets. The major income tax provisions available to farmers provide an important means of reducing variation in after-tax net cash flow and should be included.

It might be argued that interacting the several levels of simulation models will be too time consuming and expensive for consideration. However, Kite and Roop have described models that might be used to estimate the impact of certain inflationary forces on input and product prices at the farm level. Detailed simulation models developed for more conventional firm growth studies are available for some typical farms to assess the impact at the firm level. The availability of models suggests interacting the aggregate and firm-level models may be quite feasible.

Basing the farm-level analyses on specific sets of price changes would estimate differential impacts of inflation for alternative resource situations including land qualities, tenure, size, equity, etc., as desired. This approach is a potentially richer source of data on the firm level impacts than using models which ignore shifts in production methods and product mix, production and price uncertainty, and income tax effects. The approach would estimate the rate of return to land, labor, capital,

and management by size and type of farm rather than assuming they are constant in real terms for all farm types over time as the O'Carroll model does.

Microeconomic Impacts of Inflation on the Food and Agriculture Sector: Discussion

Michael L. Walden

The topic of inflation and its impacts has received a great amount of attention by the public and the media for obvious reasons. Unfortunately, much of the discussion provided in these forums has been misdirected with respect to the meaning, causes, and consequences of inflation. The economics profession is looked to for guidance and analysis that will aid both private and public decision makers in deciphering the meaning and implications of inflation.

The paper by Kite and Roop represents an attempt to apply the analytical tools of the profession to measuring the impacts of inflation on a particular economic sector, here the food and agriculture sector. Unfortunately the work is flawed in several major aspects. Most significant among the paper's problems is the authors' failure to conceptualize and define inflation properly. Kite and Roop claim that inflation has its origins in microeconomic price increases, i.e., "microeconomic price increases in one sector, through their initial effect on consumer demand and their direct and indirect effects on costs of intermediate materials in other industries, can lead to inflation in the macroeconomic sense." As an example, they cite the standard description, often presented by the popular press, of how oil price increases permeate the economy, causing complementary increases in non-oil factor inputs, wages, and product prices—in short, general inflation.

Clearly, this conceptualization and causal explanation of inflation is contrary to the most elementary principles of macroeconomics. The refutation of the oil price (or for that matter, any other factor input) argument as a cause of inflation hardly needs repeating. In brief, increases in the price of any factor input (e.g., oil) will be followed by price increases in all products only if the monetary authorities accommodate the original price increase with increases in the money supply; in the absence of such an accommodation, higher expenditures on oil products can be realized only by lower expenditures, and demand, on non-oil products. The result is a rise in oil sector prices balanced by a fall in non-oil sector prices and no change in the average price index (Levi, pp. 59–60).

The fundamental problem with the Kite-Roop conceptualization of inflation is the failure to distinguish between "inflation" and "price changes." Elementary economic theory teaches us that any individual product price change can be decomposed into two parts: one part caused by nominal, or money, changes, and a second part caused by real (demand and supply) changes in the individual product's market. Only the former influence is properly termed an inflationary impact; i.e., inflation is properly defined as a rise in the general price level resulting from macroeconomic changes. If general price level changes, or changes in its stimuli (i.e., money supply) are properly measured, then its impact should be on a one-to-one basis with individual product price changes. Recent research supports this hypothesis for aggregate agricultural prices (Grennes and Lapp) and for retail food prices (Belongia and King). Product price changes different from changes in the general price level are caused by real supply-demand shifts in the product's market. Admittedly, some of these real effects may arise from an interaction between general price level changes and institutional factors in the product's market (the interaction of the investment tax benefits of homeownership and land and "bracket creep" produced by inflation are the best examples). Any investigation into the impacts of inflation on individual product prices should attempt to sort out these sources of change. Interesting research questions concern the lag structure of the nominal inflationary impact (see Belongia and King)

Michael L. Walden is an assistant professor in the Department of Economics and Business at North Carolina State University.

and the effects of institutional interactions with inflation.

The failure to distinguish between nominal and real aspects of price changes plagues the Kite-Roop analysis throughout. In essence, since Kite and Roop do not distinguish between nominal and real impacts, price changes which they label as "inflationary" are really an aggregate of nominal and real effects. Changes in agricultural support prices, changes in real income, and changes in agricultural input prices do not represent changes in inflation (properly defined). The closest that Kite and Roop come to modeling the impacts of inflation is their simulation involving an increase in the overall CPI index. However, in simulating this effect they hold nominal income constant, hence not recognizing that inflation is a neutral nominal increase in all prices, including the price of labor. Therefore, Kite and Roop never do investigate the topic of their research; that is, they never do investigate the microeconomic impacts of inflation.

It is difficult to judge adequately the two simulation models without seeing a copy of the equations, parameter estimates, and the analysis on which the parameter estimates are based. Therefore, several questions and concerns come to mind with respect to the models. How is inflation generated in the models? When an individual real price rises, do the models assume that the real price change will be accommodated and spread throughout the economy via nominal inflation impacts? What is the structure of the monetary subcomponent and how does it interact with other parts of the model? Do the models adequately compensate for labor productivity and technological changes? For example, Belongia found a causal relationship between retail price increases and increases in nominal wages in excess of the growth rate of labor productivity in only one commodity group. How do the models handle the interaction of inflation with institutional arrangements which may produce nonneutral impacts from inflation? For example, do the models simulate the changing investment patterns of households during inflation? What theoretical assumptions are implicit in Kite and Roop's use of "mark-up" rules for pricing between wholesale and retail levels, and are these assumptions justifiable? Last, how have the models been validated, and what were the results?

In light of the above criticisms and questions, it is not possible to make informed comments regarding the results of the simulations. Instead, let me conclude by presenting an outline of a research strategy for investigating the microeconomic impacts of inflation. First, any such research must be properly grounded in economic theory; this involves a proper conceptualization of the differences between "price changes" at the microlevel and "inflation." Second, such research should include an understanding of the macroeconomic causal forces affecting inflation, which necessitates an incorporation of money supply generation and growth. The latter is particularly important because the money supply is a policy variable which can be manipulated by policy makers to influence the rate of inflation. Last, such research should attempt to separate and measure the impacts of nominal and real factor changes on microprices. The aforementioned research by Belongia and King and Grennes and Lapp already represents fruitful work following this approach.

Technical and Decision Aids for Local Decision Making
(Judith Collins, EES, U.S. Department of Agriculture, Presiding)

Management Information Systems for Local Government

Arlo Biere and John Sjo

For some time private firms have used computer-based comprehensive management information systems. Local governments also have used computers to process data, but local governments lack comprehensive management information systems—for several reasons: (*a*) they have not had or have not allocated resources to develop such systems; (*b*) the nature of local governments make such development difficult; (*c*) interstate differences in local governments make it difficult to design systems that can be used nationally; (*d*) local governments lack incentives to acquire such a system; and (*e*) private vendors have not developed and marketed such systems as they have for private businesses.

Here we discuss local governments' need for assistance to develop management information systems, constraints that keep them from adopting such systems, and how adoption might affect local governments' capacity. We describe briefly the management information system we developed for and instituted in county governments in Kansas and conclude by discussing the role of economists in system design.

Local Governments Need Assistance

System development and implementation is complex and time consuming. Such a system consists of (*a*) a management organization description that specifies flows and uses of management information, (*b*) software to handle the data described above, and (*c*) a computer to process the data. The first of the three is most critical. How well the management system is organized and understood will determine the limits of the software performance and the computer's usefulness in handling expected tasks. Except for large metropolitan governments, a local government lacks the resources—financial and technical—to develop its own management information system. Attempts to modify systems developed for private firms have not been successful because management characteristics of local government differ too much from those of a business in at least five ways.

Local governments have no single objective measure of performance as do private firms. In business, profit is a measure of performance and of capacity because the entrepreneur's objective is to produce profits. Also, that profit motive provides harmony of purpose among all managers within a business. Governments are formed to provide services to citizens. For them, profit is not a reasonable measure of performance and no other measure is a good substitute. It is hard to measure performance other than by voter satisfaction, which tends to be *ex post*. Lacking an objective performance measure, various participants in local government—elected officials, bureaucrats, and citizens—each may have a different concept of a local government's purpose. That lack of a single performance measure and of a harmony-of-purpose control factor requires a more complex management information system as no single indicator contains all crucial information.

Local government decision making is a political process where the decision makers are both internal and external. So the management information system must provide information to the public (external) as well as to elected officials, appointed officials, and other employees (internal). The information needed by the public has not been determined. Lack of such information to the public may stem

Arlo Biere and John Sjo are research agricultural economists, Kansas Agricultural Experiment Station, Kansas State University.

Contribution No. 82-25-J, Kansas Agricultural Experiment Station.

from current information systems not being capable of providing it in a way it can be used or from government officials not wanting to make full disclosure, which would reduce their discretionary power.

The political process of decision making produces a sense of discontinuity because leaders are elected and the election of an opposition candidate may result in certain programs being discontinued. That potential for discontinuity may cause employees to concentrate their efforts on short-run strategies. An information system can provide incentives to develop longer-run management strategies.

Most governmental revenues come through coercion—taxation—or through monopoly power. Except for utilities and other services sold to the consumer, public services provide benefits so widespread that few individuals would be willing to purchase the service individually. The services are financed by taxing the citizens so the acquisition of resources does not depend directly on consumer satisfaction with the service. Accountants describe this condition by saying that expenditures for such services do not generate revenue as does a product produced for sale by a private firm.

Because revenues to finance such public services do not come from the sale of the service, state legislatures grant local governments authority to levy taxes for specified purposes. Fund accounting is used to segregate and account for such money as it is received and disbursed. Other public services, like utilities, may generate their revenue, but a local government that produces and sells those services usually has a monopoly. So, whether the service is financed by taxes or by selling the service, there is no competitive market pressure for efficient production. For a government to have an efficiency objective, it must be an explicit objective because economic efficiency is not implicit in the governmental process.

Because of the way resources are obtained and because of the importance of the political process, the annual budget is the central tool guiding government expenditures. It has more force than a budget in private business where it is just a planning tool. When a local government adopts its annual budget, it establishes the spending authority (appropriations) for the next year. Expenditures must be within the appropriations. Exceeding the original budget is difficult. Legislative action by the local government is required to change appropriations, and state administrative approval may also be required. With a budget serving as such a strong control, comparisons of actual expenditures with the budget allocations guide expenditure decisions.

The strong annual budget influence restricts governmental administrators in making long- or intermediate-run decisions. Long-term planning is further inhibited because governmental officials do so little of the actual budget development. In Kansas we find that county budgets are prepared by an outside auditor consulting with the board of commissioners and other officials. The auditor is hired to prepare the budget because, with current information systems, budgeting is so difficult and complex. So, while the process of budget preparation offers the best opportunity to establish long-run plans, much budget preparation is turned over to an outside auditor or financial advisor.

From the viewpoint of an administrator, the annual budget process produces temporary property rights (appropriations). An administrator runs two risks when making expenditures from appropriations: exhausting the full appropriation before the end of the budget year, and not expending the full appropriation by the end of the budget year. Those two risks can dramatically influence an agency's efficiency.

Statutory and regulatory provisions are prominent in local government affairs. State statutes and administrative rulings govern the conduct of business in local governments. Two such examples are state standards regarding accounting and state laws and regulations governing the property taxation process. A management information system must be designed to meet such requirements.

Statement 1 of the National Council on Governmental Accounting, issued in 1979, says the basic financial statements of a governmental unit should be prepared to conform with generally accepted accounting principles. When financial statements so prepared do not demonstrate statutory and regulatory compliance, the unit shall prepare additional schedules to demonstrate such compliance. That clarified an earlier position taken by the Municipal Finance Officers Association that accounting systems should first satisfy statutory and regulatory requirements. Although the clarification has simplified accounting

problems for local governments, most local governments still use a single-entry, cash-accounting system. A challenge facing many states is to get local governments to adopt generally accepted double-entry and accrual accounting practices.

A management information system designed to meet the needs of local governments can contribute to the more effective and efficient operations of local governments. But local governments differ so much from private firms that it is not feasible for a local government to adapt a management information system for a private firm to its needs. Because most local governments do not have the resources to develop their own management information systems, land grant universities can do that, just as they have helped individual farmers to improve management on their farms.

Constraints to Adoption

We found local governments planning to adopt a new management information system must deal with the high initial cost of a new system, delayed benefits, stresses the new system has on the administrative structure and on affected personnel, and possible quick obsolescence of the new system.

Adoption of a new system means investing in equipment, software, supplies, and personal training. Initially, extra effort must be expended to put data into the new system and to make the gradual transition from the old to the new system. That may mean additional labor costs for the first year, when benefits received from the system are smallest. The benefits of the new system will not be realized until personnel can use it proficiently and know how to use the information produced. Another benefit after the first year is that some data, such as voter registration and real estate assessment data, need to be entered only once and updated thereafter.

The management information system must be consistent with the unit's organizational and operational procedures. When not, the inconsistencies must be reconciled. For some inconsistencies, unsatisfactory procedures should be discarded, e.g., abandoning single-entry cash accounting. Because a high degree of standardization of procedures is used in computer processing, some procedures acceptable with manual processing may not be acceptable with computer processing. Adoption of a new system provides the opportunity to improve governmental operations. Stresses on the administrative structure may not be welcomed and may create conflicts between offices if the new system changes the relationship between offices. Education for the changes and consultation with concerned individuals can help to avoid new conflicts between offices, to speed acceptance of the system, and to avoid rejection of the new system before benefits from it are realized.

Implementation of a rational system places new strains and risks on decision makers. Argyris has concluded that a rational management information system can create conditions where executives experience (*a*) reduced freedom of action, (*b*) a sense of psychological failure because of the management system's constraints, and (*c*) a decreased feeling of importance as they see (*d*) emphasis on leadership based on competence instead of formal power so familiar to managers. Those implementing a management information system must cope with the emotional stress the system produces—for themselves and their employees.

A local government considering a new management information system may already have had unpleasant experiences in adopting new methods of data processing. During the 1970s many local governments purchased computers expecting to solve their data problems only to be disappointed with the results. For some, disappointment turned to exasperation when they learned that the purchased equipment was depreciating 30% or more per year. Such an experience has caused some officials to be highly skeptical of new technology.

Role of Management Information Systems in Capacity Building

McDowell identified development of management information systems as one strategy to increase the capacity of a local government. Biere and Sjo discussed how information systems impact capacity by drawing an analogy to the general welfare economics model. Here we discuss the impact of improved management information on capacity by studying the definitions of capacity and their implications. Honadle reviewed several definitions of capacity and concluded that no consensus definition appears in the offing. Instead, she offers a framework for thinking about capacity build-

ing. Capacity, she says, is the ability of a local government to anticipate and influence change, to make intelligent decisions about policy, to develop programs to implement policy, to attract and absorb resources, to manage resources, and to evaluate current activities to guide future actions.

To expand on Honadle's framework, we suggest considering the differences between the concept of the firm and the Robinson Crusoe example. When considering the capacity of a private firm, one usually refers to its ability to produce a certain volume of a good or a service or of a bundle of goods or services. That is really an intermediate measure of capacity. From the viewpoint of the entrepreneur, a firm's capacity would be defined relative to his objective so it might be measured by profit or a related measure.

Within Honadle's framework there is a similar ultimate objective for local governments. Her definition of capacity refers not to an intermediate measure comparable to the volume of goods and services produced by a private firm, but an ultimate objective that justifies the local government's existence, which is not the same as it is for a firm. In the case of the private firm, production is separated from consumption and price serves as the informational link between consumption and production. Profit can be determined readily as the firm, by using market prices and input-output rates, can compute the value of the output and the value of the resources consumed. That profit provides a measure of capacity and an indication of the firm's ability to survive.

Local government is more similar to the classical Robinson Crusoe example of a man who makes production and consumption decisions in combination. As a producer of public services, the local government must make production decisions. As an institution for public decision making, the local government determines what public services shall be provided—at what level and to whom—and how the services are to be financed. The latter function distinguishes a local government from a firm. But production and consumption decisions can be difficult to separate. With does not separate a decision on road improvements from providing for the improvement through the road department.

We find Honadle's definition and most other definitions of capacity to be based on a concept of a local government analogous to a private firm. Such a concept fails to recognize the more crucial role of making public choices regarding the level and mix of public services and regulations and how they will be financed and enforced. Those issues have impacts that are embodied in those five characteristics of government discussed previously and that greatly add to the complexity of a management information system and make it more difficult to determine its adequacy.

Although the Robinson Crusoe example is more appropriate than the private firm example, the Robinson Crusoe example ignores the high human interaction in operating local governments. Involved are citizens, elected officials, political party officials, special-interest group members, and employees of the local government. Those employed in government recognize that the government does not have a single measure of performance and that the decision-making process is complex. Those conditions give each employee much latitude to interpret his duties and to justify his performance. Furthermore, management controls and information systems for government tend to be less developed than for a private firm. Those conditions have remarkable parallels with the five basic elements of Leibenstein's micro-micro theory of production: (*a*) Individuals in the organization are selectively rational. (*b*) Individuals in the organization are the basic decision units. (*c*) Each individual in the organization has discretion over his effort. (*d*) Individuals in organizations may be inert to organizational pressure. (*e*) The organization is subject to organizational entropy or the natural tendency toward disorganization.

Those five conditions make it desirable to consider the individual as the fundamental decision unit, not the local government. Then, the outcome of local government activities reflects the aggregate of individual actions. A good management information system should help the organizational structure to aggregate

human interaction present. The role of the management information system is to provide information to assist managerial control of the production activity and to provide relevant information regarding public issues to all who participate in the decision-making process. But the information needs may differ in each case. To inform citizens so they can make intelligent collective decisions requires different information from management information necessary to guide government's internal operations.

The lack of management information systems for local governments seriously detracts from this governmental capacity. It is our premise that developing and adopting management information systems will contribute to local government's capacity by providing information so citizens can make more informed decisions and by providing a control mechanism that assures that the local government operates to produce selected public services efficiently and effectively.

Kansas Local Government Information System

In 1975 the Board of Commissioners of Ellis County, Kansas, invited the Kansas Agricultural Experiment Station to develop a new management information system for that county government. The board previously had purchased two small computers to handle the county's data processing. County officials were frustrated by the limitations of the computers, by increasing reporting requirements of the state, and by finding that data processing on the new computers was not fully compatible with the county's needs. County officials had thought the computers acquired would solve their data handling and management information problems. Instead, they created more problems!

The first product of our work was a report on the organization and operation of the Ellis County government, including a study of statutes pertaining to the management of a Kansas county. Ellis County's operation and organization were tested against those statutes. When the county's operation or organization conflicted with state statutes, we met with county officers to reconcile the differences.

The second product of our work was a restructured management information system, consisting of procedural manuals and computer software to perform the needed data processing. The manuals are organized by major components of the management information system. Each volume of the manual reviews key statutes affecting that part of the management information system, lists the objectives, and describes both how to use the component and the steps to using the system, including how to prepare originating instruments, to key data, and to obtain reports.

The county keys data at the courthouse and transmits the data for processing by telephone on a remote job entry terminal to a central computer at Kansas State University. Most print jobs are transmitted by telephone back to the courthouse. Large print jobs, such as printing tax rolls, tax statements, and tax receivable files, can be done at the central computer. Remote processing was chosen because it offered greater capabilities and because the county was relieved of the cost and responsibility of operating a computer in a courthouse. That choice originally gave the county no local computing capabilities. New remote entry terminals can be used both to transmit and receive data and to process small jobs locally. We are scheduled to add a cash register to the system this fall to capture data on cash received in the treasurer's office.

The system has six subsystems (see Sjo and Biere): a name file, taxation, accounting, payroll, physical assets accounting, and voter registration. The financial portions of the system are fully integrated, designed to leave an audit trail, and to provide data security. The accounting subsystems are designed to conform to generally accepted accounting principles (GAAP) as given in *Governmental Accounting, Auditing, and Financial Reporting.* Also, the accounting subsystem is designed to permit a user to obtain cost accounting by office and by job category within an office.

The name file, a supporting subsystem to the taxation system, is a computer-maintained list of the persons, firms, and organizations with which the county conducts transactions.

The taxation subsystem is used to keep assessment records, to levy taxes, to record tax collections, to abstract taxes levied and taxes collected by taxing districts, to process delinquent tax accounts, to prepare tax warrants and tax sales, and to record collections on tax warrants and tax sales.

The accounting subsystem is a double-entry fund accounting system. Revenue and estimated revenue transactions may be recorded also by office receiving the revenue. All ex-

penditures, encumbrances, and appropriations are recorded both by fund and by office. Each office is treated as a cost center. It is then possible to obtain the full expenditures made by any office, and those expenditures can be identified by the fund the expenditures were made from. An office also may designate a job code to identify in that cost center the activity that incurred the expenditure.

The physical assets accounting subsystem provides an inventory of each physical asset item. It can calculate depreciation on depreciable fixed assets. Such depreciation is used for cost analysis only.

The payroll is processed through a payroll agency fund. Labor service expenditures are recorded in the accounting subsystem as transactions between the payroll agency fund and the funds from which labor services and associated benefits are paid. Various employee reports are available such as leave used, W-2 reports, name directories, individual employee reports, various fringe benefit and deduction reports, and needed quarterly reports. The system can handle salaried or wage-earning positions. Records of hours spent on various tasks can be kept for cost accounting.

The voter registration subsystem is used to maintain a county voter registration file. It is used to print primary and general election registration lists, to print city and special district nonpartisan or partisan lists, and to abstract voter rolls by voting precinct and by political party.

The complete system has been in use by Ellis County for nearly two years. It is being implemented in another Kansas county which is changing from a completely manual system. That implementation experience shows the need to provide substantial training and assistance for the county to adopt the system smoothly.

Economists' Role in System Design

During our work, we have observed that the design and development of the management information systems for local governments have received little attention from economists, even though much of what such systems are about is in the purview of economics. Such systems are concerned about resources used and products produced, about providing incentives to participants to do what furthers objectives of the entity as determined by the public-choice process, about information flows required to obtain desired coordination among elements of the entity, and about public information needed for enlightened public choice.

The foundation for the design of a management information system is the description of local governments, including crucial characteristics of the local government, the political process by which decisions are made, the internal and external management information needs, the information necessary to determine—at least to encourage—efficient production, and the gamut of alternative arrangements by which a public service might be provided or a social objective met.

The study of local government, public choice procedures, and management needs involves political science and economics. From them is determined the management information needed—that for internal management and that for citizen action in the decision-making processes. The internal and external information desirable should include information regarding the efficiency of resource use. Here the issues of resource use, labor specification, capital intensity, employee incentives, alternative production techniques, and the objective functions of each participant in the operation are important.

Better cost information permits local governments to choose among a wider range of alternative ways to obtain a public service economically, such as by contracting with a private firm or with another local government for the service.

While information is useful, all is not of equal value. Information should be produced to the point where the marginal value of the last unit produced is equal to the marginal cost to produce it. At least it should remind us that more information may not be good.

Most management information systems are now computerized, and the complexity of computer programming deters the study of management information systems by those not proficient in computer programming. But the role of the computer in a management information system is just to capture, store, manipulate, and print or retrieve information. The computer is used because it can handle large volumes of data cheaply. Management information system design and requirements can be specified without a computer. Manual prototypes can be used initially to illustrate the steps: how and when data are to be captured, how and when data are to be stored, and how

the data are to be retrieved and used. Once those have been specified, a computer specialist can prepare programs to do those jobs.

Economists have a useful role to play in the design of management information systems for local governments. New management information systems should enhance the capacity of local governments. That potential is more significant now that local governments may receive less federal money. But the development of such systems takes time and an understanding of the role of the management information system in governmental operations. By working with political scientists, management experts, and computer specialists, better designed and more comprehensive systems can be developed to meet challenges facing local governments.

Decision Aids for Local Decision Making

Gerald A. Doeksen and James R. Nelson

Rural areas and small communities had a higher population growth rate during the 70s than metropolitan communities. This is the first time this had occurred in 160 years. Preliminary 1980 census figures indicate that nonmetropolitan counties increased in population by about 15%, whereas metropolitan counties increased by about 9% from 1970–80. However, rural growth has occurred selectively. Many mining, resort-retirement, and urban fringe counties grew by 40% or more in the 70s. On the other hand, nearly 500 of the 2,485 nonmetropolitan counties continued to decline in population during the same period (Secretary of Agriculture).

Decision makers in rapidly growing counties or communities are faced with the task of planning for growth. This includes estimating future growth and associated needs for community services so that sufficient capacity can be built into public service systems. Decision makers in declining areas face an equally difficult task of maintaining services for their constituents. Many of these communities are in heavily agricultural areas and lack alternative sources of employment. The reduction of population often leads to a decline in the economic base and in resources to support services.

Decision makers in both growing and declining rural areas need assistance in planning to accommodate change. A program to provide such assistance is ongoing at Oklahoma State University (OSU). Rural development decision aids developed and utilized at OSU fall into three main areas and include (*a*) prediction of growth or analysis of impacts of changes in economic base, (*b*) derivation of budgets for alternative community service delivery service systems, and (*c*) generation of information in administration of delivery systems.

If such decision aids are to be developed and maintained for use by extension personnel, it is imperative that a strong research base be available to keep the research current and to develop new decision aids. The objectives of this paper are (*a*) to discuss each of the types of decision aids specified above, (*b*) to review the importance of a solid research base in the development and maintenance of such decision aids, and (*c*) to discuss extension delivery techniques for rural development decision aids.

Decision Aids to Predict Growth

For long- and short-range planning of community services, it is important that local decision makers have the best employment, income, and population estimates available. A mistake of building a water or sewer treatment plant too small or too large can be costly and embarrassing to elected officials. They need the best estimates with which we can provide them.

Many community service needs are a function of the age of the population. For example, the number of school children in a community can be estimated from information on the number of children by age category. For these purposes, a demographic model that includes components of births, deaths, and migration can be used. Migration is difficult to predict, but historical migration can be projected in lieu of more appropriate information.

If there is a change in the economic base or the structure of a community, more detailed models may be needed. Some of these include economic base, input-output, from-to, dynamic input-output, or simulation. Shaffer developed a local development model understandable by local decision makers. Applicability of Shaffer's work has been proven by the widespread adoption of the basic model. Similar models were computerized by personnel at the University of Florida, Purdue, South Dakota State, and Texas A&M.

Gerald A. Doeksen and James R. Nelson are professor and associate professor, respectively, in the Department of Agricultural Economics at Oklahoma State University.

Professional Paper Number 1059, Oklahoma Agricultural Experiment Station.

The authors would like to thank Luther Tweeten and Dean Schreiner for their helpful suggestions and comments.

Presently, at OSU, we are using an input-output model and community service use coefficients as decision aids in long-range rural development planning. An example of an application of our decision aids is a recent study for Weleetka, Oklahoma (Lenard, Doeksen, Hodges). A new electrical equipment-manufacturing plant is scheduled to employ 52 workers in 1981, 122 in 1982, and 175 in 1983. An input-output model was used to predict the secondary impact for employment and income. The employment estimates are presented in table 1. Based on local conditions, such as unemployment and family size, population changes were also projected.

In addition, the impacts these changes have on community services were projected. Examples of impacts on community services are presented in table 2. Estimates were made of sewer needs, fire calls, hospital bed days, physician office visits, solid waste generation, and school taxes which would be attributable to the new plant. Local leaders used the estimates to evaluate the adequacies of local community services.

As researchers, we need to continue to improve our basic models and as extension workers we need to relay the needs as we perceive them from the user level to researchers. Our local level background has convinced us of needs for (*a*) more in-depth localized information about the impacts of economic change and (*b*) more information about the dynamic impacts of development or decline. Researchers are moving in this direction. An example is the regional model developed to analyze coal development in North Dakota (Toman, Murdock, Hertsgaard). Murdock and Leistritz are refining this model to measure the economic and demographic impacts on three communities of a nuclear repository. A community simulation model is being developed at OSU (Woods and Doeksen). A gravity model is used to estimate the service area of a community; then location quotient and input-output techniques are combined to constitute an economic model. The economic portion of the model is made dynamic by a recursive system of equations which are driven by final demand-estimating equations. The demographic portion of the model is based on a population model employing births and deaths. Migration is used to fit the demographic portion with the economic portion of the model. The model predicts employment and income by industrial sector, population by age cohorts, community fiscal measures, and community service needs. Fiscal measures include the amount of revenue generated by source, such as sales tax or user charges. Community service information includes predictions of needs for water, sewer,

solid waste, fire, ambulance, police, hospital beds, and physician visits.

Decision Aids to Evaluate Alternative Community Service Delivery Systems

The decision aids employed most frequently by Oklahoma rural development extension personnel are community service budgets. Farm management research and extension personnel have employed budgets for years and they are the foundation of many of their programs. Likewise, we have found that they are the cornerstone of our community service programs.

In Oklahoma, research and extension personnel in recent years have emphasized providing budgets for community services, and responses from local decision makers have been overwhelming. Now that local decision makers, state personnel, and others have become aware of our capabilities, requests for budget studies are almost more than personnel can handle. For example in 1980, Oklahoma Cooperative Extension Service personnel completed over 100 specific community service budget studies. These budget studies serve not only to build a clientele for rural development extension but also to provide a needed service. A recent letter from the mayor of Durant, Oklahoma, attests to this fact. The letter to Charles Browning, Dean of Agriculture, reads:

> We wish to express our appreciation of your fine staff and their report, in regard to the ambulance study for Bryan County. The data they collected and the information they presented will be most helpful in our determination of how to handle the situation. We will probably use their experience again at a later date.

To illustrate the results of a budget study, a recent emergency medical services (EMS) study will be summarized (Lenard et al. 1981). The research base for the extension application is found in an EMS handbook (Doeksen et al.).

The city council of Sayre, Oklahoma, requested a budget analysis of their emergency medical service. They were seeking the best delivery system for the least cost. The study included an analysis of all ambulance runs made during the preceding year. Data were analyzed by a computer program and calls were sorted by type, time of day, place of pick up, destination, response times, and other criteria. The information aids a system manager to plan for staffing and equipment needs.

Next, an estimate of future calls was made to give decision makers an idea of future capacity needs of the system. Methodolgy derived from the research project was used to estimate calls for 1981 (fig. 1). Ambulance calls were classified into three types: (*a*) highway accidents, (*b*) transfers, and (*c*) other medical calls. Highway accident calls were specified as a function of the number of autos and motorcycles in the service area. Transfer calls were defined as the movement of patients between hospitals and were specified as a function of the size and services of the local hospital, the local medical staff, and other medical factors. Transfers can be estimated from records of the local hospital. Other medical calls included all other calls and are generally for emergency reasons, such as heart attacks and strokes. These were found to be a function of age. Using nine age categories, utilization rates were derived which indicate the number of calls per 1,000 population. These utilization rates can be used with area population data to predict the number of other medical calls. By applying the methodology, 406 calls were estimated for the Sayre EMS in 1981. In addition, a demographic model was employed to estimate the population of the area from 1980–90. Using the methodology in Doeksen (1979) the number of EMS calls was projected. For example, there were projected to be 449 calls in 1985 and 498 calls in 1990.

The research base allows for the prediction

		Total other medical calls	289

D. Total ambulance calls: 39 (highway calls) + 78 (transfer calls) + 289 (other medical calls) = 406

Figure 1. Application of EMS research to Sayre, Oklahoma

of costs and returns for alternative systems. Forms were derived for easy analysis and presentation. The summary form is presented in figure 2. The top portion of the form can be used to estimate receipts. For example, if a $55 base rate is charged plus $1 per mile one way and 70% of the patients pay their bills, $24,045.00 will be collected. Annual capital and operating costs for four alternative systems are summarized on the bottom portion of the form. The first alternative involves a system with volunteers and paid personnel. Total estimated annual costs equalled $56,674.98. The second and third alternatives include volunteer systems whereas the last is a hospital-based system.

In this example, if 70% of patients pay their bills and a $65 base charge plus $1 per mile is employed, none of the systems would break even. Another source of income or a subsidy of some sort is needed at the $65 base rate.

The budget analysis presents the alterna-

Three locations	23.5	1.6	23.5	1.7

tives confronting the local decision makers. The alternatives are constructed to reflect their desires. In addition to EMS budget studies, extension personnel at OSU conduct budget studies for fire services, clinics, water delivery, solid waste disposal, transportation systems for the elderly, and sewage disposal (Doeksen and Nelson).

Decision Aids for Administration of Delivery Systems

As we worked with decision makers, requests involving other decision aids surfaced. In each case, research was undertaken to develop the aids that could be used in future applications. Requests surfaced concerning (*a*) optimum location of emergency equipment, (*b*) least-cost service routes, and (*c*) potential revenues associated with alternative rate structures. Each of these is discussed below.

Optimum Location of Emergency Equipment

The decision makers of Bryan County (Lenard et al. 1980) decided to create an EMS district to serve the entire county. Location of ambulances is critical to providing the best quality service. Local leaders requested a study to evaluate alternative locations. A general transportation model was used to minimize a linear objective function with respect to specific linear constraints (Oehrtman, Broeckelman, Doeksen). For Bryan County, there were seven possible ambulance locations. These were Caddo, Bokchito, Bennington, Durant, Calera, Colbert, and Achille. Once the supply points (locations) were designated, it was necessary to delineate demand areas. These were assumed to follow township lines within the county. This procedure resulted in the creation of thirty demand areas. Road miles from each of the seven supply points to the center of each demand point were computed to determine a mileage matrix. The remaining data needed by the location model are the number of annual calls for ambulance service expected from each demand area. These were estimated as a function of area populations. The computer model was run to determine the least-cost combination of locations.

If two locations are desired, the locations which yielded the lowest estimated average response time are Bokchito and Durant (table 3). By having vehicles at these locations, the estimated average response in miles was 2.4 miles and the maximum was 23.5 miles. The three locations to minimize average response time were Bokchito, Durant, and Colbert. Estimated average miles to an emergency dropped to 1.6, whereas the estimated maximum distance remained unchanged. First- and second-choice solutions are presented. In addition to providing quality of service data as reflected in the response times, costs are estimated for each system. The annual cost of providing service from two locations was estimated as $167,519, whereas the annual cost if service is provided from three locations was estimated as $187,618. Local decision makers must decide whether the increased cost is worth the reduction in response time.

Least-Cost Service Routes

Another decision aid which was developed to meet local requests is a routing model (Oehrtman, Broeckelman, Doeksen). Requests have been received concerning appropriate routes for solid waste trucks and school buses. A recent example of applying the problem to a school system with 102 bus stops to pick up 219 children is used to illustrate the model. Each bus has a capacity of 48 children; therefore, assuming one route per bus, five buses would be required to transport the children from their homes to school and vice versa.

All bus stops were numbered, and the num-

Form II
Procedure Used to Compare Estimated Annual Receipts and Costs for Alternative Ambulance Delivery System

	Alternative Fee Rates			
I. Estimated Receipts	$45	$55	$65	$75
Ambulance Fee $___ x (___number of calls) =	18,270	22,330	26,390	30,450
Mileage Fee ($1 per mile one way)	12,020	12,020	12,020	12,020
Total Receipts	30,290	34,350	38,410	42,470
Receipts at 70% payment	21,203	24,045	26,887	29,729
Receipts at 60% payment	18,174	20,610	23,046	25,482
II. Estimated Costs	1st alternative	2nd alternative	3rd alternative	4th alternative
Specify vehicle	Hightop 2 Vans	Hightop 2 Vans	Hightop 2 Vans	Hightop 2 Vans
Communication system	VHF	VHF	VHF	VHF
Labor system	Partially Paid	Volunteer	Volunteer	Hospital
A. Capital expenditures				
Vehicle depreciation	$8,145.00	$8,145.00	$8,145.00	$8,145.00
Communication (Base)	$563.50	$563.50	$563.50	$563.50
Communication (Vehicle)	$530.00	$530.00	$530.00	$530.00
Building Depreciation	$3470.00	$3,470.00	$3,470.00	$3,470.00
Pagers	$530.60	$530.60	$530.60	$530.60
Interest	$_____	$_____	$_____	$_____
Subtotal	$13,239.10	$13,239.10	$13,239.10	$13,239.10
B. Operating Expenses				
Vehicle	$8,531.50	$8,531.50	$8,531.50	$8,531.50
Communication	$450.00	$450.00	$450.00	$450.00
Building	$1862.88	$1862.88	$1862.88	$1862.88
Medical	$3755.50	$3,755.50	$3,755.50	$3,755.50

C. Labor costs Subtotal	$28,330.	$9,366.	$7,300.	$23,460.
D. Training cost	$250.00	$250.00	$250.00	$250.00
E. Miscellaneous	$250.00	$250.00	$250.00	$250.00
Total	$56,674.98	$37,710.98	$35,644.98	$51,804.98

Figure 2. Summary form of EMS alternatives facing decision makers in Sayre, Oklahoma

ber of children to be picked up at each stop was indicated. In addition, a mileage matrix was specified which indicated the miles from each bus stop to each other bus stop. The computer routing program was then used to select the five routes which would minimize miles traveled without exceeding bus capacity or time limits. The five routes specified by the computer program minimize the mileage traveled by the five buses.

A Utility Rate Structure Model

The estimation of revenues associated with community services that have complicated rate structures (such as water systems) can be

a rather complex procedure. A computer program was developed at Oklahoma State University for this purpose.

In order to make the program operable, data must be input on number of users and consumption by user for each month in a year. Alternative rate structures can then be specified and the computer will calculate total revenues which would be generated from these users from each rate structure alternative (Nelson et al.).

Decision makers for Ottawa County Rural Water District Number 2 in northeastern Oklahoma requested assistance from the Cooperative Extension Service in estimating revenues which they might expect from alternative rate structures. They wished to compare these revenues with estimates of costs for upgrading their system. The decision makers provided appropriate data on system use.

Computer outputs such as the one shown in table 4 were then generated for several rate structures. Water district decision makers used this information to set new water rates.

Importance of a Research Base

An extension program which delivers decision aids to local leaders needs a strong and continuing research base. Rural development researchers need to continue (*a*) improving decision aids by better prediction of community growth and decline and evaluation of impacts, (*b*) updating and improving community service budgets and analyses, and (*c*) providing new decision aids as new problems surface. A community simulation model is needed which is sensitive to many local issues and can predict important variables over time.

Concerning our community service budget analysis, much research work remains. Specific needs are (*a*) to provide better demand or usage coefficients, (*b*) to determine if a service is price elastic or inelastic, (*c*) to estimate economies of size, (*d*) to estimate at what usage levels additional capital inputs are needed, (*e*) to provide quality of service measurements, and (*f*) to continually update budget data.

The Delivery Process

Other than the usual procedure of having the requests go through the county extension director with assistance provided by the area and state rural development specialist, several features are thought to be critical to successful delivery of rural development decision aids by Oklahoma Cooperative Extension. These include (*a*) a team effort involving all related agencies, (*b*) rapid responses to requests, and (*c*) specific community reports. When a request is received, OSU personnel involve all related agencies. For example, if an emergency medical service request arises, personnel from the State Health Department, State Highway Department, Health Systems Agency and Sub-State Planning District be-

Table 4. Total Water Sales (Dollars) by Month and Use Class

Month	Less Than 1,500	1500 to 4,500	4500 to 6,500	6500 to 10,000	More Than 10,000	Total
January	803	1,281	398	293	125	2,899

December	660	925	675	660	446	3,366
Average	600	768	610	779	887	3,644
Total annual: $43,732						

Note: Information is based on the following price scheme: under 1,500 gallons: flat rate of $7.50; next 3,000 gallons are charged at $0.110 per 100 gallons; next 2,000 gallons are charged at $0.080 per 100 gallons; next 3,500 gallons are charged at $0.075 per 100 gallons; above 10,000 gallons charged at $0.070 per 100 gallons.

come part of a response team. Each agency has expertise to contribute to the solution of a community problem. Community leaders are impressed by such joint efforts and recognize to whom they may turn if questions arise in specific areas. Since this approach is working, other agencies are aware of our contributions and often refer budget studies to us.

Local leaders appreciate quick response to their crises. Many of the studies have been computerized to facilitate rapid response (Nelson and Doeksen). The goal of extension personnel has been to complete a study within four weeks of the date the request is received. In addition, a computer terminal is often taken along to a community when a final report is delivered, so that other alternatives can be analyzed via telephone connection if community leaders so desire. The computer programs are written in interactive modes so they are easily used and understood by local leaders.

The last, unique aspect of the delivery process is to leave copies of final reports with community leaders. Reports include names, agencies, and telephone numbers of everyone involved with the report. Written reports are good advertisements for extension as leaders from other communities see the reports and become aware of the assistance which extension can provide.

These decision aids have built a strong and large clientele. Many community leaders have written the dean of agriculture or the president of the Oklahoma State University indicating their appreciation of extension's assistance. If we ever need someone to "go to bat" for rural development extension in Oklahoma, we are confident that the many community leaders for whom extension has worked will gladly support our programs.

Management Information Systems for Local Government: Discussion

Steve W. Murray

Sjo and Biere have skillfully discussed a topic which is timely since there are intense public demands for more efficiency in the production and delivery of services by local governments, for a reduction in the size of public sector, and for an accompanying reduction in taxes. Community development researchers and extension personnel at land grant universities are concerned that local government officials in smaller cities trying to operate more efficiently may purchase expensive computer hardware and software which have limited applications in local government and may not provide government administrators and voters with useful information for making decisions.

A management information system must furnish relevant data in useful form to the right person at the right time for use in management decisions. Computers assist in the process but, as Sjo and Biere explain, the computer itself is not the management information system. To be effective the system must supply administrators with information they need to deliver services efficiently (an "internal" use) and it must transmit information about the cost of the services to the voters (an "external" use). Through the political process the mix and level of services can be adjusted so that the total utility of the community is maximized.

There are levels of sophistication of computerized management information systems. At the first level the computer does what was formerly done by hand or with noncomputerized equipment. Even though the size of the application might be quite large, this is still the lowest level of computer utilization. In this mode the computer functions as a high-speed adding machine and typewriter.

At the second level the computer is used to automate a portion of an agency's work. This includes the use of the computer as a low level decision maker in those instances where all the factors needed to make a decision can be programmed into the system and judgmental qualities are not needed. Examples of automated applications are the automatic sending of overdue or cutoff notices for delinquent utility bills, permit application renewals, and summonses for parking violations after prescribed periods of time.

At the third, and highest, level the computerized management information system reports to managers the types of analytical information that will help them in their work of decision making. The computer is used to make aggregations, summaries, and exception analyses for these purposes.

In most local governments the computer is used at the lowest level; Sjo and Biere challenge economists to see that higher utilization is attained. The economist must be a partner with the data-processing professional, the accountant, and the attorney in designing the management information system for local government. The first requirement is that the system maintain records which are required by federal, state, and local statute. This is a low level usage and the economists' contribution is limited at this stage.

The economists' contribution is critical at the third level—providing analytical information to government administrators and voters. Typical of the contributions the economist can make in the development of the management information system is clarifying the effect of depreciation and interest expense on the total cost of providing various services.

Sjo and Biere argue that local governments have no single objective measure of performance as do private firms. They maintain that profit is a reasonable measure of performance for private firms and question whether other measures are good substitutes. Local governments provide distinct services. Some of these services are readily available in both public and private sectors. Examples of ser-

---

Steve W. Murray is a community development specialist, Mississippi Cooperative Extension Service.

vices which are commonly provided by either sector are solid waste collection and disposal, road and street construction and maintenance, and emergency ambulance service; services commonly produced only by the local public sector are fire protection and operation of the polls. Local decision makers must routinely choose whether to provide public services such as those in the first category indirectly through contracts between the government and the private firms or directly by employees and equipment of the local government. The information the local decision maker needs is not related to profits, but rather to the total cost of providing the service by the government as opposed to the contract price charged by the suppliers of the service in the private sector.

The authors stress that there are fundamental differences in the objectives of managers of private firms and the objectives of administrators within local government organizations. For example, while the objective of the manager of a private firm may be to maximize profits, the companion objective of a public sector manager may be to provide adequate service while spending exactly the amount allocated to his department during the period covered by the government budget. The vendor of the computer must understand that objectives of government administrators differ from those of managers in private firms. Government officials must understand that software designed for private sector applications may not be useful in a government department.

Whether universities, the federal government, or private firms will lead in the development of computerized management information systems for local government is uncertain. Because of their training and contacts with local government, extension and research economists at land grant universities certainly can contribute to the development of local government management information systems.

Management Information Systems for Local Government: Discussion

Richard Barrows

Sjo and Biere have taken the initial steps in developing a conceptual framework relating management information systems (MIS), local government capacity building, and a general theory of local government behavior. To their credit, the authors avoid the common error of focusing on computer technology, technique, and case study examples rather than on the policy issue or problems MIS is designed to resolve. They have produced a thoughtful and stimulating paper.

My major criticism of the paper is simply that the analysis of the governmental setting for MIS was not sufficiently developed. This criticism is not entirely appropriate, given the constraints on the length of the paper and the initial stage of development of the conceptual framework. I will briefly extract what I believe to be the key points of their argument, suggest some modifications and avenues for expansion, and identify some implications for research and extension.

The authors note some critical differences between private businesses and local governments that affect adoption of MIS. Two of these differences form the basis for an argument that the neoclassical theory of the firm will not perform well when applied to local government decisions in general, and MIS in particular. They argue that for local governments, an "objective performance measure" analogous to profits for firms is lacking because of widely divergent views of what local government should do. A second important observation, that "local government decision making is a political process . . .", leads Sjo and Biere to the conclusion that various definitions of "capacity building" are inadequate because they are based on a concept of local government analogous to a private firm. They argue that the Robinson Crusoe example, in which consumption and production decisions are made in combination by a single entity, is a more appropriate conceptual model. However, they criticize this concept because it ignores the high degree of human interaction inherent in local government operation.

A generalized model of local government decision making is implicit in the paper, although it is never explicitly or fully developed. I will extend some of Sjo and Biere's arguments and outline a model similar to those developed recently in international relations in political science (Allison). Consider a local government which jointly makes consumption decisions (which services, how much, to whom, etc.) and production decisions (how to produce, by whom, what cost, etc.). Consider a political environment in which decisions are the result of the interaction of various interest groups, private organizations such as businesses, public organizations such as county departments, elected officials, and the "interested public." This interaction is structured according to some "rules of the game" which define the channel through which an action is taken. Action channels vary with the issue. For example, the action channel for a road construction project decision will be different from that for a federally financed sewer project. These decision-making rules place individuals or groups at key points in the process and partially define the power or access to power of individuals, interest groups, and organizations.

This rudimentary model can be applied to adoption of MIS. Sjo and Biere correctly note that those "external" to government bureaucracy are central in consumption decisions and that MIS must be designed to help citizens make collective decisions. (However, public agencies also participate in the consumption decisions). For a given consumption decision, it is possible to identify the action channel, the key actors along the channel, the private interest groups and organizations, and their

The author is a professor of agricultural economics, University of Wisconsin and a natural resource economist, University of Wisconsin Extension Service.

interests. This should aid in a systematic identification of relevant information for a MIS system. For example, in Wisconsin county forest decisions, the relevant actors are the county board chairman and forestry committee, recreationists, loggers and wood industries, resort owners, and a state agency. Each group has some fairly well-defined interests that should be captured in any MIS design.

Production decisions are also best viewed as a political process. Adoption of a particular policy or action may simply shift the political struggle to the implementation front. Also, as Sjo and Biere note, production occurs in complex organizations and the theory of organizational behavior pioneered by Simon and others is relevant. In designing an MIS, it is important to understand both the local political process and decision making within complex organizations. (Sjo and Biere argue that the individual is the basic decision unit in production, not the local government. In small rural counties, where one individual may comprise an entire county department, this may be a useful simplification of organization theory, but in larger counties this may not work well.) Obviously, MIS also can assist in analyzing the efficiency or cost-effectiveness of production activities. However, if MIS is to be used to provide incentives for efficient production, then an understanding of how individuals act in complex organizations is required.

The view of MIS as a part of local government political processes suggests two obvious research needs—a conceptual model of the local government decision-making process and a model of behavior in complex organizations adapted to rural, small government conditions. Both types of research are well-suited to interdisciplinary work by economists and political scientists, as Sjo and Biere note. Extension economists also would benefit from research to identify the "key ingredients" for successful implementation of an MIS system. One key ingredient may be a strong incentive for local government to adopt MIS—in Ellis County, Kansas, it was evidently strong dissatisfaction with a new computer system. A strong incentive probably is needed to overcome the problem of short-run costs and long-run benefits from MIS, and the short-run nature of government budgets and the terms of elected officials. Another prerequisite may be strong support from top administrators and staff, and the incentive and ability to absorb the training necessary to make the MIS system work. Sjo and Biere's example also suggests that some outside support may be necessary at least in the first few years in the first counties to adopt MIS. The challenge for extension economists is ultimately to design a procedure for design of MIS which can be used by local governments or private firms without extensive university support.

Decision Aids for Local Decision Making: Discussion

W. Arden Colette

The authors have done an excellent job of documenting what can be done and is being done to assist local decision makers. Their presentation refers to more than twenty alternative analyses they provide for both the private and the public sectors. The list of available decision aids is impressive and the developers of the programs should be complimented.

However, the state of knowledge is never static. There is always a search for a better mouse trap or a better model. The authors' list of research needs demonstrates the need for constant improvement. The development of more precise demand and usage coefficients, the computation of elasticities, the determination of economies of size and other economic measurements would be helpful in refining and improving the decision aid models.

The program described by the authors was developed and has been operated successfully in a system in which the extension specialist completes the analysis and presents the alternatives to the decision maker. However, they do not consider future trends in decision aid development and use nor do they address the implementation of programs under different extension philosophies or where personnel are limited.

Universities that are contemplating initiating or expanding their decision aid programs should answer four basic questions in their planning process. First, who will bear the costs of the program? The cost can be borne by the community that uses the decision aid (and thereby receives the benefit), by the state program, or it can be paid out of federal funds. The distribution of costs will affect the number and size distribution of communities that participate in the program. Second, will a fee be charged for the service or will the service be provided free? If a fee is charged, will it cover the cost of developing and using the aid or will the community pay only the variable costs? If the fee does not cover the entire cost, how is competition with private consultants to be evaluated? Third, will education or service be the basic extension philosophy of the program? In an educational program, the decision aids would be developed and local personnel trained to use them. In a more service-oriented program the analyses would be run by university personnel and only the alternative solutions presented to the decision makers. Fourth, what will be the level of service? Will the programs provide expertise by substituting for local planning departments or will it develop expertise by providing only supplemental information for professional planners?

The answers to these questions will go a long way in determining the types of decision aids to be developed, the form they should take, and personnel needs.

During the past few years computer technology has progressed so rapidly that independent computer systems are now within the financial reach of even the smallest planning department. Depending upon their size and the complexity of their tasks, decision makers can select between microcomputer, minicomputer, and main-frame computer systems. A leading planning consultant has predicted that during the 1980s the use of the personal computer will become standard in even the smallest planning office (Finn). Even at the current level of technology the microcomputer provides many alternatives for geographic-based data display, planning data analysis, office operations, and telecommunications.

Regardless of the method selected, the university has a role in satisfying those information needs that are beyond the scope of any single local planning department. Local planners look to the university to obtain population projections and other demographic infor-

Florida Agricultural Experiment Station Journal Series No. 3336.

mation. There are also basic data sets that are needed by all planners. Basic technical relationships, such as school services requirements, housing services needs, water requirements, sewer generation, trip end generation, and secondary impact multipliers are common requirements of all planning units. The development and maintenance of these types of data sets should be one of the basic functions of every university program.

One of the main problems that every program must face is the development of receptive clientele and adequate support. Unlike Oklahoma, many programs have not been able to generate strong political support from clientele groups.

In summary, the paper is an excellent documentation of what can be done and how far decision aid development has advanced. However, it provides little insight into the future direction of decision aid development and program implementation. In expanding its program, each university must answer such questions as, Who will bear the cost of the program? Will the program be primarily educational or service oriented? What level of service will be provided? And, finally, how can strong clientele and financial support bases be built and maintained?

Decision Aids for Local Decision Making: Discussion

Josef M. Broder

In this period of declining state and federal support for many local programs, local officials are given the formidable task of providing adequate levels of community services for localities which often exhibit unique and unpredictable growth patterns. More than before, local officials must assume the role of entrepreneurs in planning and implementing community service delivery systems. As with any type of management role, the local decision maker has an ever-increasing need for management information. The quality of a particular decision with regard to community service provision is only as good as the quality of the information available to the decision maker. Unfortunately, many small units or subunits of government have neither the information or the means of obtaining the information for making sound management decisions.

Realizing the importance of information to the local decision-making process, Doeksen and Nelson have developed an impressive program of decision aids for local decision making. The main thrust of their program is to assist rural areas in planning to accommodate change. Their program emphasizes three main areas which include decision aids (*a*) to predict growth, (*b*) to evaluate alternative community service delivery systems, and (*c*) to administer delivery systems. This discussion will attempt a brief assessment of the strengths and limitations of these decision aids. In conventional terms, area (*a*) is concerned with the demand side while areas (*b*) and (*c*) are concerned with the supply side of community service provision. Given the collective nature of community service provision, this discussion is written from a public choice perspective.

With respect to demand, the authors have indicated that population, employment, and income changes impact directly on the level and mix of community services. Local decision makers face a twofold challenge of satisfying the majority needs of current residents and planning for potential growth. The latter of these challenges appears to be the most troublesome. In planning for populations and industries which may (or may not) arrive at some future date, decision makers are faced with the problem of planning for option demand. Option demand is a special public goods problem associated with identifying and collecting a fee from individuals who will benefit at some future date from a public decision made today. For expanding communities, planning for option demand means designing and financing service delivery systems which exceed the effective demand of the current population. This task is further complicated by uncertainties as to the preferences of future residents which may differ from those of current residents. Reliable growth forecasts can reduce some potential overinvestments or underinvestments in service delivery systems.

On the supply of community services, Doekson and Nelson discussed decision aids to assist decision makers in evaluating and administering alternative systems. For this purpose, community service budgets were developed which enable decision makers to choose among alternative systems. Adopted from farm management budgets, community service budgets eliminate some of the guesswork associated with implementing or increasing the level of community services. Lacking the resources to generate budget information, local officials will be able to use these decision aids to provide services at lower costs. I was particularly impressed with the format and thoroughness of the budgets designed for ambulance delivery systems. Particularly noteworthy of these budgets are the decision options which are made available to decision makers. These options provide considerable flexibility for decison makers.

After adopting a service delivery system,

Josef M. Broder is an assistant professor, Department of Agricultural Economics, University of Georgia.

decision makers need information on monitoring and modifying the system over time. To this end, research was undertaken to enable decision makers to determine optimum locations, least-cost service routes, and potential revenues. Optimum locations for emergency medical services were determined through a general transportation model. A computer routing program was developed to minimize travel costs for solid waste trucks and school buses. A computer program was developed to estimate potential revenues from alternative water rate structures.

Some major shortcomings of these decision aids were discussed by the authors in their needed research section. Among the more important were (*a*) the need to provide better demand estimates and (*b*) the need to provide quality of service measurements. Given a clearly defined objective function of maximizing revenues or minimizing costs, the service supply problem reduces to a farm management problem. However, when citizens disagree as to the proper level and mix of services, the process of community service provision may not be as simple as the authors have indicated.

A distinction is made in the public choice literature between production studies which establish physical input-output relationships and institutional studies which are concerned with conflicts over output definition under alternative institutional settings. The decision aids developed by the authors are sufficient for identifying production relationships but are weak in assisting local decision makers to understand the community service demand-articulation process. Without a clear understanding of citizen preferences, local decision makers risk maximizing the level of community services citizens do not want. In addition to production studies, decision aids are needed which enable decision makers to identify citizen preferences.

The demand articulation process affects both the quantity and quality of community services. Service quality is a reflection of how well the level and content of a service meets the preferences of local citizens. Service quality is influenced by the preferences of citizens who have access to the community service production process. Changes in population likely will change the relative power of groups and their access to this process, and, thus, further complicate the task of providing quality services compatible with majority preferences. More research is needed on the impact of community growth on the service demand articulation process.

In conclusion, local decision makers also need decision aids that enable them to identify changes in community preferences and adjust the level and mix of community services accordingly. These decision aids can take the form of preference surveys of the type used by national level decision makers to identify majority preferences on a particular issue. Survey technologies can be readily adapted to the local level. The development of local preference surveys as decision aids will further enhance the decision maker's ability to provide community services which are consistent with local needs.

panels and an advisory committee were formed. The study was organized around three areas: (*a*) management of food and agricultural research, (*b*) structure of food and agricultural research, and (*c*) determination of food and agricultural research priorities.

A work group of nationally recognized professionals was formed for each of the three areas. The work groups identified the topics of the commissioned papers, advised on the major components of each paper, and recommended authors. Each work group also reviewed the papers and drafts of the final report.

An overall advisory committee also was selected. It included research professionals and representatives from sectors affected by food and agricultural research—farmers, processors, retailers, labor, and consumers. The advisory committee provided overall guidance to OTA on issues to be analyzed, and it reviewed all commissioned papers and drafts of the final report.

Although the report does not focus on agricultural economics per se, there are a number of observations that can be made about the role of agricultural economists in the broader area of agricultural research. The remaining discussion will delineate the contributions by agricultural economists to the study, discuss some of the general findings of the study that have relevance to agricultural economics, and discuss implications for the agricultural economics profession.

Contributions of Agricultural Economists to the Study

The major contributions of agricultural economists to the OTA study were in three main areas.

First, an economist with a strong interest in agricultural history traced USDA and state research institutional developments and showed their growth and interaction over time.

Second, agricultural economists were responsible for (*a*) analyzing the funding of agricultural research; (*b*) analyzing the costs, benefits, and burdens of agricultural research; and (*c*) developing methodologies to measure the quality of research. Under (*b*), agricultural economists analyzed the nature of research benefits, examined the distribution of benefits and burdens, studied the relationship between benefits and funding sources, and measured the economic returns to research investment. Under (*c*), agricultural economists attempted to develop better methodologies for measuring the quality of research through the use of publication citations in peer-reviewed journals and the granting of patents. A great deal of research will be needed before these or any other measurements of research quality can be used, if they can be used at all.

Third, agricultural economists evaluated methodologies for determining research priorities. Existing methodologies—for example, those used in the World Food and Nutrition Study—were evaluated according to their strengths and weaknesses. Again, it became evident that more research is needed to develop methodologies for setting research priorities and to assess the impacts of the research.

In general, we were somewhat surprised by the relatively limited amount of research on the social, economic, technological, and other impacts of agricultural research in the United States. We particularly have in mind rate of return, or cost-benefit analysis, and development of methods for measuring priorities. Much of the major existing work concerns foreign agriculture; the relative neglect of the United States is rather odd, considering the early work of Griliches and the University of Minnesota research conference held in 1969 (Fishel). Much of the work reported at a recent Minnesota conference for this country (*Evaluation of Agricultural Research*) was of a scattered nature and recent vintage. Research on the impacts of agricultural research in the United States does not seem to yet be a main line of activity in the profession.

Assessment References to Agricultural Economics

The assessment made a number of findings. Although economics research was not a main focus of the study, it did come in for some attention. Those findings of particular interest and with implications for economics research are briefly noted here. They are in the areas of funding, roles of research participants, management of research, and research priorities determination.

Funding

Despite the fact the USDA was a pioneer and long a leader in research in the U.S. government, the present situation is quite different.

Recent USDA research expenditures have been the smallest of any major federal research agency. In 1978, USDA's share of federal research expenditures was only 1.5%. This compares as follows: Department of Defense, 45%; Department of Energy, 16%; and Department of Health and Human Services, 12%.

The purchasing power of total USDA and SAES agricultural research expenditures increased 23% in constant dollars from 1966 to 1979. The pattern, however, differed sharply by component: USDA expenditures increased only 1%, while those of SAES increased 40%.

Private industry agricultural research is a major contributor to total food and agricultural research in the United States. Total expenditures by private enterprise for food and agricultural research are about three-quarters of the expenditures of state and federal government combined.

Within the total research budget of USDA (excluding funds passed on to the states), economics research as represented by the Economic Research Service (ERS) occupies a relatively small role. From 1972 to 1980, it accounted for only about 5.5% of USDA research expenditures.

Economics research typically has not been strongly favored by the agricultural committees in Congress. Other forms of social science research have been even less favored. Congressional disfavor originated with early efforts by the Bureau of Agricultural Economics (BAE) to be a general planning agency for the department. This proved to be highly controversial and was gradually cut back. From 1953 to 1961, economics research was split between and assigned to the Agricultural Research Service and the Agricultural Marketing Service.

In 1961, agricultural economics research was regrouped into the Economic Research Service and the Statistical Reporting Service (SRS). While the new arrangement was quite attractive to many agricultural economists, it did not find great favor in Congress. When Willard Cochrane, the first Director of Agricultural Economics, left in 1964, he said that without strong support from the Secretary, ERS would have a difficult time surviving, in part because "ERS had no pressure group "You insist on having a Bureau of Agricultural Economics. It is my judgment it costs you about a million or a million and a half dollars a year to carry that title, because it is hard to sell" (Baker and Rasmussen, p. 67).

Only rarely did an appropriation that increased funding for a particular line of economics research get through the Congress. As for the regular ERS budget, Congress continued to be critical. "The administrator sometimes seemed to be on a treadmill where great effort was required merely to remain in place" (Baker and Rasmussen, p. 68).

In fact, economics research funding through ERS has not even done that well. From 1966 to 1979, current dollar expenditures by ERS increased rather steadily from \$16.3 to \$37.1 million, or 127%. However, this increase did not keep up with inflation during the period, and in constant dollars there was an 8% decrease from 1966 to 1979.[1]

Moreover, of the roughly 5.5% of the Department's own research budget for 1972 to 1980 that was spent by ERS, only part was spent on research as such. ERS estimates that in FY 1980 only 35% of its funds went for research, 47% for analysis, and 18% for data acquisition. If these proportions are applied to the FY 1980 budget, it means that only 2% was spent on economics research and that the other 3.5% was spent on economic-related activities. There are no widely accepted norms in these matters, but this does seem a very small proportion for economics research.

The economics departments in the colleges of agriculture at the land grant universities have not fared much better. Economics research has remained at about 7.3% of total funding for all agricultural research in the United States since 1970. Other social science research has accounted for 2.0% of total expenditures, while biological and physical science research has received 89.9% of the total expenditures within the USDA and state agricultural experiment stations.

Roles of Research Participants

There is an important role for a strong national research program funded by USDA. This role has been carried out in the past by the Agricul-

tural Research Service (for a while known as SEA-AR[2]), Economic Research Service, and federal funding to state agricultural experiment stations. Historically, the ARS role was associated with broad regional, national, and international activities. The role of SAES, insofar as federal funds are concerned, has been primarily for local, state, and regional problems.

Within agricultural economics research, there has been very little discussion on the roles of the major public participants—ERS and university departments of agricultural economics. ERS convened a national committee of department chairmen and researchers in August 1979 to discuss mutual problems and interests. One issue was a perceived misunderstanding about similarities and differences in the role of ERS and university departments of agricultural economics. This lack of understanding was viewed as a barrier to improving the linkages and communication between ERS and universities. Several stereotypical descriptions indicated the differing perceptions of the group: (*a*) ERS works on national problems, and universities work on local and regional problems. (*b*) Universities work on micro problems and ERS on macro problems. (*c*) Universities should conduct basic and methodological research, and ERS should conduct applied research. (*d*) ERS serves national policy maker clientele, and universities serve farmers and state policy makers.

It is clear that the agricultural economics profession is not in agreement on what the roles are or should be for ERS and the universities. A clarification of roles should make it easier to identify areas of mutual interest and facilitate productive cooperative research.

As an example of the delineation of roles, there is no question that there is a role for a strong national USDA research program in the physical and biological sciences in food and agriculture. There are some implementation problems; but when the system is working properly, federal funds allocated to ARS are primarily for problems of regional or national importance where (*a*) the nature and/or magnitude of the problem is such that a single state cannot provide the resources for its solutions, (*b*) ... concerns for the problems, or (*c*) from an industrial standpoint, where the risk is too high or too demanding for any one industrial component. ARS is also responsible for research needs of action agencies within USDA. In addition, it is responsible and accountable to both the executive and legislative branches of government for the administration and national coordination of such programs. ARS leaves to the states those local, state, and site-specific problems that can be handled by the SAES.

SAES, insofar as formula funds are concerned, have primary responsibilities for state or local problems. SAES are concerned with problems of a regional, national, and/or international nature that are an extension of their state and local problems. But where ARS has active regional and/or national programs, such programs are developed cooperatively.

Agricultural economists need to debate the merits of a similar demarcation between ERS and universities. There have been no follow-up activities since the 1979 meeting. The tightening of federal funds in social science research will no doubt force this type of debate as appropriations committees demand a more efficient and coordinated approach to research.

Management of Research

During the long existence of the Bureau of Agricultural Economics and since 1961, agricultural economics research has been a separate research component in USDA. (Between the two periods most of the economics research was integrated into the Agricultural Research Service and the Agricultural Marketing Service). University departments of agricultural economics are also organized separately from the other disciplines. One result from this type of organization has been some isolation from the rest of the agricultural research community.

The discovery of new knowledge does not come as easily and in such small disciplinary packages as it once did. Modern agricultural research tends to be mission-oriented and multidisciplinary—involving the commitment

between ERS and ARS.[3] In fact, with the exception of some ad hoc groups that meet sporadically, there is no coodinating mechanism for planning and conducting multidisciplinary research between ERS and ARS.

There may be more opportunities for disciplinary blending at the land grant universities. Certainly one would expect the SAES to try to encourage it. But on the other hand, the disciplinary walls established in graduate programs, where much of the research is done, can mitigate against the needed blending, and the research problems may be bigger than can be handled by the usual Ph.D. program. Thus it may be, as Paarlberg has suggested, that land grant universities have not organized themselves to combine well in a modern setting the two functions of developing agricultural economists and discovering new knowledge.

To obtain increased federal support in the future, something more may be required than the greater lobbying effort of the past. Coordination of research among the scientific disciplines needs increased attention.

Research Priorities Determination

At present there is no continuous long-term systematic planning process for food and agricultural research. Decisions are made on an ad hoc basis with very little coordination among the USDA, SAES, and other federal and nonfederal agencies conducting food and agricultural research.

Systematic determination of research priorities is important. Some research needs must be given higher priority than others. Requests for across-the-board increases for each scientific discipline will not be convincing to the appropriations committees. In fact, such requests have disillusioned them in the past. Such requests appear as more of a defense of the research bureaucracy than an earnest effort to solve the most important food and agricultural problems.

Many planning efforts exist, but none address the total spectrum of agricultural research as a unit. For example, the USDA and the land grant universities, under the auspices of ARPAC, had a system of regional and national research planning committees to identify needs in all areas of food and agriculture. However, the classification system used did not delineate the economics problems per se and, consequently, it is not possible to compare planned research with research needs for economics. Further, there has been no improvement in interfacing economics research with the total agricultural research planning of the Joint Council.

Congress established the Joint Council on Food and Agricultural Science and the National Agricultural Research and Extension Users Advisory Board to aid in coordination and priority setting. These groups have struggled with their assignments. The Joint Council has had difficulty organizing for its responsibilities, and the impact of the Users Advisory Board is unclear. Neither of these organizations has the capability to conduct a long-range systematic study of research priorities that involves scientists, research administrators, users, and consumers.

Involvement of the above participants is critical to the establishment of priorities. Scientists and research administrators are needed for the obvious reason that they have the expertise and are the performers of the research. The users of the research are needed because they have specific problems that need to be addressed by research. Consumers and other groups, such as labor, are an important aspect because they are affected by the research. Their voices have not been heard in the past and they have legitimate research concerns that the research community needs to address.

Long-term research planning can be accomplished by an intensive, comprehensive study involving the above participants. Such a study could involve the use of methodologies such as those pioneered by the National Academy of Sciences World Food and Nutrition study for priority determination. It might be updated every four years with a final report delivery date of 1 December of the year of each presidential election.

Priorities established in the long-range study could serve as the basis for authorization and budget hearings with the Congress and give direction to the total research effort.

Similarly, in the agricultural economics profession there have been little, if any, collective and systematic identification and prioritization of important problems. Individual researchers and individual research organizations give attention to emerging issues and to research that will be needed to address them. But there is no systematic process to coordinate these efforts

[3] ERS does include some research in the other social sciences (particularly rural sociology) and in history, but not a great deal

among institutions and individual researchers nor to see how much agreement or disagreement there is on what should be the future research agenda.

Agricultural economists evidently have never developed a process for problem identification in agricultural economics research. Agricultural economists should seriously consider initiating a major effort to identify emerging issues and economic research needs. Some proposed initiatives have been discussed, but they need to be given much more consideration.

Some Implications for Agricultural Economists

In the course of the OTA study, we gained some impressions about the role of agricultural economists in the broader arena of agricultural research. They might be considered hypotheses which require further discussion and testing.

The first overriding impression, already noted, is the need for much more research on the impacts of agricultural research by the profession. Curiously, the field did not originate in USDA or in the land grant colleges, but rather at a private city university, the University of Chicago. And most of the early practitioners were either former Chicago students who found positions at land grant colleges or students of former Chicago students. The field has grown some in recent years, but outside of a couple of universities it is principally composed of a few scattered individuals. ERS is still doing virtually nothing directly in the area (although it helps generate some of the data needed for such analyses). It is vital that more effort and resources be devoted to this line of work if we are to better understand and measure the contributions of agricultural research.

A second impression is that agricultural economists have been too insular; they are too isolated from the rest of the agricultural research community. We must note immediately that there are numerous individual exceptions. But, as a whole, it appears that many members of the profession do not have close ties with scientists outside their departments. We suggest that agricultural economists need to work closely with other social sciences and the humanities and with the biological sciences. We hear of interdisciplinary work, but we do not see much of it.

Agricultural economists, along with a relatively few rural sociologists, are virtually the only social scientists normally to be found within the public agricultural research structure. The other social sciences have significant contributions to make: we have in mind anthropology, geography, history, philosophy, and political science. Yet no agricultural college has a significant commitment to these subjects: at most, there may be one or two persons in these fields elsewhere in the university with an interest in agriculture.[4] They seldom receive any funding from the agricultural experiment station.

This situation probably reflects a lack of understanding about the potential contributions of these disciplines to agriculture and concern with possible legislative reaction on the part of research administrators. But even agricultural economists, who might be expected to be somewhat broader in their outlook toward other social sciences, have not appeared to be forthcoming. There seems to be little or no effort to build a more broadly based and integrated rural social science.

The agricultural economics profession as a whole, in general, also appears to have surprisingly limited links with the biological and physical sciences related to agriculture. This may be seen in the relatively limited interchange between agricultural economists and agricultural scientists at land grant universities and within USDA (ERS is particularly guilty). Agricultural economists seldom draw on biological scientists for insights or work closely with them in structuring their work.

One would expect a fair amount of agriculture in agricultural economics. This seems to become less so over time. Knowledge of agriculture and agricultural science almost appears to be of decreasing importance in the profession. At one time there was not very much economics in agricultural economics; now there is often relatively little agriculture. As we have become purer economists as a profession, we also stand in danger of becoming less useful to agriculture.

In generalizing about the relative scientific isolation of many agricultural economists, we must acknowledge that there are numerous individual exceptions. Groups are more difficult to identify. One group has done exceptionally well—the agricultural economists

[4] The Food Research Institute at Stanford, a private institution, has long found a place for demographers and geographers among its economists. On the other hand, it has no biological scientists.

at several of the international agricultural research centers sponsored by the Consultative Group on International Agricultural Research.

These institutions are primarily biological research organizations. Economists were added gradually and gingerly. The economist was initially alone, or virtually so, in a sea of biologists. He had to talk with them and work with them. The center director was primarily interested in what the economist contributed to the direction and conduct of the overall research program. The economist had to adapt to a new and rather strange world. And to the surprise of many, he did. More economists were added and their influence has grown. And some have had their work recognized in the form of awards from this association.

Moreover, some of the centers have recognized the importance of other social sciences and have gradually begun to add other social scientists, particularly anthropologists. One center has renamed its broadened economics unit the Social Science Department.[5]

One of the main themes of the international section of the overall OTA report is that the United States has much that it will be able to learn from the expanding program of agricultural research elsewhere in the world. This may also be true of agricultural economics.

Concluding Remarks

There is concern in Congress that all is not well in the food and agricultural research sector. This concern resulted in a request by the Congress for the Office of Technology Assessment to conduct an in-depth study. Many of the study's findings have implications for agricultural economists. Generally there is a need for more research on research and development of methodologies for measuring priorities. There is a need for delineating the roles of the university departments of agricultural economics and that of the Economic Research Service. There is also a need for greater involvement between agricultural economists and other social and biological scientists in the agricultural experiment stations and in USDA. Agricultural economists need to work together in a systematic manner on what the research priorities are for economic research and develop a mechanism to follow through on the identified priorities.

AAEA provides an excellent forum to discuss these issues. In particular, the AAEA could organize a session at a future meeting that would focus on future food and agricultural problems, the agricultural economics research needed to provide solutions to these problems, and the roles of the research participants. These are important concerns, particularly in times of low-level funding for research. Decisions in these areas will be made. Agricultural economists need to decide whether they want to be a part of the decision-making process.

[5] Of course, not all the needed research in the international agricultural research system can be done at individual biologically oriented centers. Policy research requires a broader perspective and is carried out in a separate International Food Policy Research Institute in Washington, D.C., headed by John Mellor. This group is predominantly composed of economists.

Research and the Family Farm: Implications for Agricultural Economics Research

Lee M. Day

During the last half of the Carter administration, then Secretary of Agriculture Bergland was reasonably successful in bringing concerns about the structure of agriculture to center stage. The 1980 election appears to have lowered the place of structural concerns on the near-term policy agenda. But structural issues have been around a long time and can be expected to remain a concern of policy makers.

This paper deals with only a part of the total set of structural issues, that part dealing with the concentration of production on larger farms. In the spring of 1980, the Experiment Station Committee on Policy (ESCOP), conscious of allegations that too much of the research in the state agricultural experiment stations was of a type that was most applicable to large farms, sought a perspective on how the current structure of farming had evolved and an assessment of the role of the state agricultural experiment stations in bringing about changes in the structure of farming. ESCOP turned to a task force to develop these perspectives (Experiment Station Committee on Policy).

Chronologically speaking, the first activity of the task force was to attempt to determine the nature of research in the agricultural experiment station system with respect to possible contributions to the changing structure of farming. A 10% random sample of agricultural experiment station projects in the CRIS system was drawn. Fiscal year 1979 funded projects in both 1862 and 1890 institutions were included. Specifically excluded from that population were research projects conducted by SEA/AR, Economics Statistics Cooperatives Service, U.S. Department of Agriculture, and the research conducted by forestry and veterinary schools in the states. Directors of the originating stations were asked to classify their sample projects into one of five major categories related to agricultural production, processing and marketing, family living, community, and other.

For the first two major categories, the directors were asked to allocate the scientific year (SY) effort on the research projects among six subcategories: (*a*) basic research, (*b*) primarily useful to public bodies (e.g., agencies of federal or state governments), (*c*) oriented to small farms, (*d*) oriented to moderate-sized farms, (*e*) oriented to large farms, and (*f*) research equally applicable to all sizes of farms.

The definitions of small-, moderate-, and large-sized farms are, of course, arbitrary. We chose the gross sales measure in the belief that it is the best single measure available. Admittedly, such a measure is influenced by inflation. Also, such a measure treats different types of farms unequally. Contrast, for example, a cash-grain farm and a feed-lot operation where a major proportion of the latter's gross sales is represented by the purchase of feeder steers. The definition of small farms, under $20,000 of gross sales, was based on congressional action (the Rural Development Act of 1972, as amended). The upper limit of the moderate-sized farm at under $100,000 was based on the belief that most of the economies of size have been captured by farms of that size or smaller. All farms with sales of more than $100,000 were considered large farms.

The classification of research is by no means an exact science, but with the usual caveats about sampling errors and errors in judgment, it appeared safe to conclude that the production and marketing research of the agricultural experiment stations was not slanted toward the large farms. For example, production research represents nearly three-fourths of the

Lee M. Day is Director of the Northeast Regional Center for Rural Development, Cornell University.

The author appreciates the helpful comments and suggestions provided by B. F. Stanton.

experiment station effort. Of that production research directly related to some aspect of farming, nearly 78% was judged to be applicable to all sizes of farms; more than 10% was considered primarily useful to small farms, about 7% primarily useful to moderate-sized farms, and 5% applicable only to large farms. This is not to say that experiment station research is not making or has not made contributions to the changing structure of farming. The classification refers to the nature of the knowledge created, but it says nothing about the economic environment in which the knowledge is put to use. The task force adopted the treadmill and absorption or cannibalistic processes developed by Cochrane.

The task force concluded that even though the research effort may be characterized as producing knowledge applicable to all sizes of farms, the interaction of that knowledge with the economic environment results in a significant contribution by the experiment stations to a growing concentration of production on the larger-sized farms.

Whether the continuing trend toward concentration of production is perceived favorably or unfavorably will be decided in a larger arena than that of the American Agricultural Economics Association. But members of the profession do have a magnificent opportunity to help the public understand the issues involved by (*a*) making the current structure and changes in structure more understandable, (*b*) showing how tax and other policies designed for other purposes influence the concentration of agricultural production, and (*c*) investigating alternative ways of slowing down (or speeding up) the trend toward concentration.

The manner in which individuals and groups react to the concentration of agricultural production depends to a considerable extent on the relative weights they attach to different, sometimes overlapping, sometimes conflicting goals. Some widely held goals with respect to agricultural production are:

(*a*) Efficiency—an efficient agriculture producing an abundant food supply for domestic needs, reducing food shortages around the world and gaining foreign exchange earnings to purchase energy and other critical resources from abroad.

(*b*) Conservation—the availability of the quantity and quality of resources so that future generations can have an abundant food supply. This goal includes concerns about soil losses, farm land preservation, and depletion of energy resources.

(*c*) Employment opportunities—the availability of opportunities to work as a farm operator or laborer. This goal emphasizes the virtues of rural living, of "being your own boss," of the prospects of progressing from laborer to operator.

(*d*) Equity—the distribution of income within agriculture, and between farmers and nonfarmers. This goal expresses concern for low income consumers, for low income farmers, for reasonably equal returns for equal effort in alternative endeavors.

Individuals and groups who place a high relative weight on a particular goal may view the concentration of production quite differently from those who place a high relative weight on other goals. If agricultural economics research is to be useful in policy decisions regarding the concentration of agricultural production, it should illuminate the effects of alternative policy actions on these widely held goals.

Earlier studies of economies of size suggest that over a considerable range, size can be expanded at essentially constant costs. Farms larger than the minimum necessary to achieve those economies reduce employment opportunities (for potential farm operators as well as wage labor) with little offsetting gains to society in terms of lower food prices. A large variety of policies and programs intended for other purposes may encourage further expansion of size of farm beyond that necessary to gain efficiency and again reduce employment opportunities with little offsetting gains to society in terms of lower food prices. In a full employment economy, however, there may be gains from increased production of nonagricultural goods.

Changes in the structure of farming influence the structure of the assembly and processing system, and, conversely, changes in the market structure influence the access to markets of both inputs and outputs. The market access problem is further exaggerated to the extent that small farms produce different commodities than those to which the marketing system in the region is geared. Roadside markets, farmers markets and pick-your-own operations increase market access for a limited number of small- and moderate-sized farms. How can market access for small- and moderate-sized farms be improved?

Historically, changes in the concentration of

production on larger farms have influenced the nature of the rural community, i.e., decreased employment and wages in the local service sector. But in an era of vastly improved transportation and communication, it appears that changes in the structure of farming may also influence the development of the basic or "export" sector of the rural community. Agriculturists are fully aware that the nature of the rural community also influences the structure of farming in the surrounding area. Growth of the rural community not only converts agricultural land to residential uses, but also increases the possibilities for families to combine farm and nonfarm work in small and part-time farming operations.

This paper will not attempt to probe all the research opportunities associated with changes in the structure of farming. Instead it will concentrate on the study of economies of size in farming and on agriculture and community relationships.

Economies of Size

There are more reasons to study economies of size than to insure full employment for production economists. Many public policies are not specifically designed to change the structure of farming. Yet these policies may have indirect effects on that structure. If the indirect effects are conditioned by the economies gained by larger-sized farms, then we need to know the magnitude of these economies in order to gain some understanding of the indirect effects of such policies on the concentration of production.

For example, a price support program for corn in the first instance would increase the income of all corn producers in proportion to the amount of corn produced. If all incomes are increased proportionately there would be no initial effect on concentration. But if substantial economies of size exist, the higher absolute level of profits per unit of output, combined with the higher level of output for larger farms, will provide them both increased incentive and ability to further expand the size of farm.

Admittedly, the translation of that increased incentive and ability into actual increases in size of farms may be dependent on many factors such as tax policies, credit policies, the operator's willingness to assume risk, and the subjective evaluation of opportunity costs for the operator's family labor as well as the opportunity costs for equity in the business. Because many of these factors are themselves the subject of inquiry, e.g., tax policies, and others cannot be known by the analyst, analysis of the effects of various policies will continue to be of a budgeted or theoretical nature. But economies-of-size studies should provide essential building blocks for the conduct of such analyses.

Technical Economies

Many of the technical economies-of-size studies are outdated by reason of changes in technology as well as by reason of changes in prices paid and received. Studies of technical economies varied considerably in their definition of costs (Madden). At one end of the spectrum only cash costs are considered in the long-run average cost curve, and returns to land, labor, equity and management were treated as residual claimants; while at the other end of the spectrum, imputed costs were assigned to land, labor, equity, and management, with the risk-bearing factor the only residual claimant. The difficulties are twofold: (*a*) definition of costs may affect not only the level of the economies-of-size curve, but also the relative efficiency of small versus large farms, and (*b*) the interest in structure of farming suggests several alternative definitions of costs. For example, interest in the survival of small farms suggests the use of cash costs, particularly in areas where the availability of off-farm work is such as to provide the necessary family living expenses. Other interests, such as the size of farm necessary to provide returns to labor comparable to that in other industries, require the imputation of an opportunity cost on operator and family labor. Thus, we need not just a single economies-of-size curve for each type of farm, but rather a family of long-run cost curves reflecting different cost concepts (Miller, Rodewald, McElroy).

Miller, Rodewald, and McElroy, in a study of economies of size for field crop farms in seven regions, not only provide current estimates of economies of size, but also provide estimates of a family of cost curves representing different definitions of costs. Certainly the higher level of technology used combined with higher price levels have moved all long-run cost curves to the right, but the conclusion of the 1960s regarding a large range of nearly constant costs appears unchallenged.

While there was some variability in the shape and level of the economies-of-size curves among regions, a look at the average of cost curves for all regions may be useful. As size increased from \$59,000 to \$133,000 (an increase of 125% in sales), the cost per dollar of sales decreased 2.4¢, from 63¢ to 60.6¢. Thus, within this range the industry appears to approach a constant cost industry. Farmers in search of higher net farm incomes may wish to expand the size of their operation, but societal gains in terms of efficiency of production are minimal. The inclusion of an opportunity cost per operator and family labor at \$4.50 per hour, while increasing the level of cost, does not substantially alter the above conclusion.

There is also a need to estimate economies of size on livestock farms of various types as well as on mixed crop and livestock farms. Investigations of economies of size on these types of farms represent additional difficulties. Performance rates for labor in livestock production related to size of farms and technology uses are more difficult to come by, especially for the larger industrialized operations. Further, the methods used to estimate depreciation of buildings may have greater influence on the shape and level of the cost curves than in the case of crop farms.

Pecuniary Economies

Pecuniary economies or diseconomies are exemplified by volume discounts on the purchase of agricultural supplies and by volume premiums on the sale of agricultural outputs. But in some instances they may be regulated by federal or state governments. For example, small farms are exempted from unemployment insurance programs but larger farms must comply, representing a pecuniary diseconomy for larger farms. Other examples are environmental regulations as well as safety and health regulations. The literature on comprehensive studies of pecuniary economies and diseconomies is limited. Krause and Kyle surveyed forty-eight producers and a like number of input-output marketing farms to give some indication of major sources of economies and diseconomies on large corn farms in the Midwest. Purchasing seed, fertilizer, crop chemicals, and machinery, as well as output-marketing advantages were major sources of economies for large farms. In contrast, production labor was a significant diseconomy for larger farms. Presumably, this reflects a difference in the quality of labor. Larger farm units may very well require more experienced or more dependable labor to use sophisticated equipment. One way to reflect this in the LRAC curve is a pecuniary diseconomy. Special attention needs to be given to pecuniary economies and diseconomies because they may overshadow technical economies over a wide range of output. The difficult task will be to distinguish between pecuniary economies and bargaining power.

Tax Economies and Diseconomies

Dean and Carter, in a landmark study, have shown that progressive income taxes, when economic costs exceed deductible costs, reduce the optimal level of output. Because equity is usually greater than zero, the inclusion of an opportunity cost on equity, which is not deductible, reduces the optimal level of output. Likewise, they have shown that the higher the percentage of equity, the greater the imputed opportunity cost and the greater the reduction in optimal output. Thus, ignoring risk as a deterrent, expansion of the size of farm using borrowed capital was an attractive alternative. Using data from the Dean-Carter study, Carman has shown that increases in tax rates reduce optimal farm size and, conversely, that reduction in the rates increases optimal farm size. Thus the current debate in the Congress on tax reductions may have significant impacts on the concentration of agricultural production.

Dean and Carter also investigated the impact of taxes on the form of organization. Again, the approach was to show the after-tax economies of size for individual proprietorships and for family-owned corporations. Not surprisingly, the lower tax rates for corporations relative to the high tax rates for individuals in the higher income levels encouraged shifts to a corporate form of business organization on larger farms. Boehlje and Krause have also shown the advantages of incorporation from the perspective of growth in equity. Recent and prospective changes in the corporate tax rates are likely to increase the interest in incorporation, particularly among larger farms. But for now at least, the individual proprietorship remains the dominant form of organization.

Yet the real-world estimation of the effects of alternative tax provisions from that of other factors may not be possible. The imputation of

opportunity costs for operator and family labor and for operator capital is a subjective personal judgment not available to the analyst. Further, in inflationary periods it is the real opportunity cost of capital (not the nominal interest rate) which is relevant. Thus, the appropriate opportunity cost of capital is dependent upon the operator's expectations of future inflation rates relative to nominal rates. If real interest rates are expected to be quite low, then the imputation of opportunity costs for capital would be small and the reduction in the optimum size would be reduced. Thus, the effects of tax provisions on the concentration of production require data on operator judgments, motivations, and expectations—data which cannot be known by the analyst. Information on the effects of changes in tax policies will continue to be theoretical in nature. This may be humbling, but it should not detract from the utility to policy makers of information similar to that developed by Dean and Carter, or that using a simulation approach similar to that used by Eginton. In either case, the objectives are specific, e.g., maximizing growth in net worth or maximizing profit. Likewise, the assumptions regarding the real interest rates, the returns to operator and family labor, the technical input-output coefficients, the pecuniary economies and diseconomies are all specified. Thus, the factors deemed relevant by the analyst are clearly specified and all other factors are held constant, allowing the analyst to project the effects of alternative tax provisions on growth (Eginton) or optimal size of farm (Dean and Carter). One may question the realism of the assumptions, but the assumptions are clearly stated. The essence of the art is to choose a set of assumptions that are most likely to be considered realistic or to demonstrate the effects of alternative assumptions on the results.

Agriculture and the Community

Concerns about the concentration of agricultural production inevitably heighten concerns about the effects of concentration of production in the larger-sized farms on the well-being cern had an important bearing on passage of the Rural Development Act of 1972.

Goldschmidt had studied in 1944 two agriculturally dependent communities in California. Arvin was characterized as a large-farm community and Dinuba as a small-farm community. "The Study of Arvin and Dinuba shows that quality of social conditions is associated with scale of [farm] operations; that farm size is an important causal factor in the creation of such differences and that it is reasonable to believe that farm size is the most important cause of these differences" (Goldschmidt, p. 423).

The methodology used involved comparative case studies. The total agricultural production in the two communities was nearly identical. Very similar crops were grown, although Dinuba (the small-farm community) tended to specialize in fruit, while Arvin tended to specialize in vegetables and cotton. The two communities were located similarly with respect to highways, railroads, and cities.

The results of the study indicated that the small-farm community supported nearly twice as many business establishments, 61% higher retail trade and spent over three times as much as the large-farm community on household supplies and building equipment. Further, the small-farm community supported a larger number of people and the standard of living in the community was higher (better community facilities, more parks, more civic organizations, and more churches). Parenthetically, while the data from Dinuba and Arvin were not analyzed from the viewpoint of central place theory, there is some evidence (Goldschmidt, p. 386) to support the idea that Dinuba was a higher-order central place. If in fact Dinuba was a higher-order central place and it can be shown that the attractiveness of a community to the expansion of nonfarm export industries is related to its place in the hierarchy of communities, then some serious questions are raised about the Goldschmidt generalizations.

In the Goldschmidt study, the direction of causation is from large farms to reduced nonfarm employment and income without consideration of adjustment processes to the dis-

of the social condition (however measured) are far too complex to be attributed to a single factor such as farm size.

Heady and Sonka analyzed the effects of a number of farm-size alternatives on farm prices, net farm income, food costs, and nonfarm income generated in rural communities. They concluded that the small-farm alternative would indeed lead to greater income generation in rural communities and at a relatively modest cost to the consumer in terms of higher food costs. The income to operators of these small farms, however, would be at poverty levels. The methodology used involved a national linear programming model, a transportation sub model and an input-output sub model.

It seems self-evident that increases in the size of farm, accompanied by off-farm migration and by different shopping patterns of large-scale producers, will result initially in reduced employment opportunities, wages, and rents in the nonfarm local service sectors of some communities. The question arises, under what conditions is this a transitory or permanent condition? The answer to that question depends on changes in other basic (export) sectors in the community. From this initial condition, three alternative hypotheses are suggested: (*a*) lower wages, higher unemployment, and lower rents are insufficient to attract nonfarming basic industries into the community and people and businesses migrate to more urbanized areas resulting in a permanent depression of the level of economic activity in the rural community; (*b*) lower wages, higher unemployment, and lower rents are sufficiently attractive to nonfarming basic industries so that they migrate to rural communities, increasing employment, and causing wages and rents in the community to increase; and (*c*) lower wages and higher unemployment are insufficient to attract other industries into the community, but the aggregation of these conditions in the community and surrounding communities is sufficient to attract other basic industries to locate in one or more of the surrounding communities, so that they can draw on the excess labor supply of the overall area. The local communities which attract other industries are the beneficiaries of increased employment and income, while other communities become essentially bedroom communities with nonfarm employment limited to a few services. Certainly these appear to be relevant hypotheses, both from the standpoint of theory, and from casual observation of the equilibrating processes now taking place in rural areas.

The key to empirical testing of these hypothesized effects of farm size on rural communities is the definition of rural community. The definition is important from several viewpoints including: (*a*) the number of observations available for statistical analysis, (*b*) the availability of appropriate data sets, and (*c*) the delineation of community settings in which the alternative hypotheses might be operable. The latter is especially important because the expansion of an existing export or basic industry or the attraction of a new basic industry can be expected to be conditioned by the variety and level of services available in the community.

Historically, community studies have been more the purview of rural sociologists than agricultural economists. Sociologists think of a hierarchy of communities differentiated by the variety of institutions and social organizations. In this respect, the concepts of the rural sociologists and the agricultural economists (particularly those dealing with regional economics), appear to have some common ground. Central place theory describes the role of the central place (the variety and level of service industries) relative to the satellite places that surround it. Ignoring for the moment a hierarchy of central places, it is possible to generate some ideas about the testing of the alternative hypotheses suggested earlier. If we chose a satellite town and its hinterlands as our definition of community, then it would appear that the first alternative hypothesis of a permanently depressed level of economic activity in the community seems most likely. If, on the other hand, we choose the central place and its surrounding hinterlands as our definition of community, the second alternative appears to be a more likely candidate.

Next if we recognize the existence of a hierarchy of central places in rural areas, an index of rurality, then the third alternative (lower wages and higher unemployment are sufficient to attract other industries by the commuting process) appears to be a likely candidate.

High levels of aggregation over geographic space, e.g., state or multi-county regions, are not likely to allow the analyst to detect differences in employment changes attributable to differences in the hierarchical level of the central place. Further, definitions of community based on central place theory are not likely to

respect county lines. Federal data sets are largely county based, but state data sets in some instances provide information at a sub-county level. The Duns Market Indicator file does provide information at a sub-county level. Thus, these lower levels of aggregation based on a hierarchical scheme of central places can be expected to provide an adequate number of observations but at the expense of constraints on the data sets available for analysis.

Analyzing changes in the basic employment involves other decisions on the level of disaggregation. For example, some industries may locate near cheap labor (e.g., textiles), others may locate near intermediate inputs (e.g., food processing), and others may locate near important natural resources (e.g., steel). This implies that differences in the input mix are significant. Still other industries locate near markets. Statistical analysis, aggregating across all such industries, is likely to be inconclusive.

Further, since many of the inputs for a particular industry will come from some distance from the community, conceptualization of the supply of inputs must have a spatial component (e.g., the labor supply should include not only that labor available in the local region, but also that available from the surrounding areas). Further, a conceptualization of the supply of an input should reflect the demand of other users of that input. Likewise, conceptualizing the demand for outputs for a particular firm must reflect the supplies of the output produced by competing firms. Finally, the supply of particular inputs and the demand for specific outputs is unique to specific industries. All of this suggests that the analysis must be at a detailed level—disaggregated with respect to geographic space and with respect to industry.

An analysis of the effects on rural communities of a large-farm structure utilizing a concept of the degree of rurality and a more general framework (analyzing the kinds of industries likely to be attracted to different kinds of rural communities) will require a considerable commitment of resources. Thus, the question arises, does such an effort have real policy relevance, or is it only an example of intellectual nitpicking? The current administration has thus far been silent about rural development policy. Yet it appears that the concentration of production on larger farms will continue and the effects on rural communities will continue. It seems inevitable that this kind of research will again become high priority. In order to be ready with results when that time comes, the profession should make an investment in this kind of research activity.

No discussion of agriculture and the community would be complete without consideration of the effects of the community on agriculture—specifically the effects of growing communities on agriculture. Land use policy is the central issue. Yet the profession has not been able to suggest policies that meet the tests of effectiveness and economic and political feasibility. Perhaps we should turn our attention to investigation of incentive programs—incentives for businesses and residences to locate within the boundaries of small cities and towns rather than in the open countryside; and if they still choose to locate in the open country, incentives to locate on the less desirable agricultural land.

Summary

The continued trend toward concentration of production on larger-sized farms has many important implications for research by agricultural economists, only a few of which have been discussed in this paper. Emphasis was placed on studies of the economies of farm size, not only because the results facilitate the difficult choices between equity and efficiency, but also because they provide a vehicle for analyzing the effects of tax policies on farm size.

Emphasis also was placed on agriculture-community relationships, particularly those dealing with the influence of changes in the structure of farming on rural communities. There are reasons to believe that past studies, by concentrating on the effects on local service sectors, have overemphasized the depressing effects on the local economies. Further, the research proposed in this area would provide much useful knowledge for the guidance of national, state, and local development policies.

U.S. Food and Agricultural Research Assessment: Implications for Agricultural Economists: Discussion

Joseph C. Purcell

This paper was based on an assessment of food and agricultural research focused on three key issues with regard to food and agricultural research: (*a*) management, (*b*) structure, and (*c*) priorities. The assessment was prompted by the perception that agricultural research is not well-managed, coordination and cooperation are poor, and there is not a clear understanding of the role of the participants in the system. Thus, the assessment was commissioned to (*a*) examine and elucidate the role of the participants in food and agricultural research, (*b*) develop more efficient priority-setting or allocation mechanisms, (*c*) clarify the role of both the federal and state governments in food and agricultural research support with respect to equity, and (*d*) develop a more efficient organization and management structure.

An assessment of the assessment should raise the issues of the justification for, and how well the assessment fulfilled, its objectives. Although expenditures for support of food and agricultural research are hardly discernible on a pie chart of federal expenditures, and that allocated to the economics of food even less discernible, the Congress should be concerned with the most effective use of every tax dollar including expenditures for congressional assessments. Two facts cast doubt on the justification of the assessment: (*a*) the food and agricultural sector is a model of efficiency and has improved consistently over time, and (*b*) federal support of research is extremely small and waning over time. A more valid justification for such an assessment should have been expressed in terms of a sustained high level of performance of the food and agriculture sector and the role of the federal support to assure a continued high level of performance, given the constraints on energy and other resources and a faltering economy. The balance of this discussion is directed to a few selected items.

Impact

The paper should convey to the U.S. Congress, and especially those with an urban orientation, that continuous and adequate funding of agricultural and food research and especially economic research is in the national interest, and the benefits flow predominantly to consumers. Food production is highly specialized and moves in interstate commerce and increasingly in international commerce. The equity issue clearly supports federal funding.

The paper failed to recognize the importance of competitive forces both in the agricultural-food sector and in the undergirding research. The U.S. economy has faltered in those areas where competitive forces are weak—e.g., autos and steel. A major role of the federal government is to establish and maintain a competitive economic environment, and it clearly follows that the public sector is responsible for research. While research in the private sector is privileged, publicly supported research is readily accessible to all potential users. Publicly supported research is more efficient in that unnecessary duplication can be minimized, and public research also fosters a competitive environment. This is equally true in the marketing sector as well as in farm production. The private sector's role is to use this flow of knowledge to develop patentable products and processes. This was not clearly elucidated in the paper.

Joseph C. Purcell is a professor of agricultural economics, Georgia Experiment Station, University of Georgia College of Agriculture, and currently serves as associate director of IR-6, National Agricultural Research Planning and Analysis.

Evolution of the Agricultural-Food Sector

The evolutionary nature of the food-agricultural sector was not fully recognized in the Phillips-Dalrymple paper in terms of allocation of research funds with respect to value created, employment, etc. Initial emphasis of the research establishment was on self-sufficiency for each state. This was the way it should have been, as there was very little commerce in foodstuffs.

Specialization and large-scale production is an evolutionary process. Mechanical, chemical, and biological technologies contributed to the upward trend in efficiency of the food sector. What was not so well recognized was that a high degree of specialization required the simultaneous development of an efficient assembly, exchange, fabrication, and distribution system. In essence, about 80% of the economic (value-creating) activity associated with food is off-farm activity, and at least 50% of it is now in urban areas. Although the farm remains a vital link, the food system is no longer totally farm nor totally rural. Conversely, at least 80% of the traditional research program is still concerned with farm production activities. In dollars this is not too much, but other components are sadly neglected. The evolutionary nature of specialization and exchange requires an increasing emphasis on economic research. A viable food sector depends on efficiency in exchange and distribution and effective organization and management as well as technical efficiency. The necessity for simultaneous development in specialization in production and exchange and distribution was not fully recognized by research management nor by Congress.

Goals and Objectives

The paper alludes to the failure of the research establishment to identify clearly goals and objectives. The confusion surrounding goals may well be a failure to recognize that the agricultural-food sector is a component of the larger socioeconomic infrastructure. Thus, the implicit and directional goals of the greater society apply to all its components. Paramount among the greater societal goals is that of economic development, or rising affluence. Research directed to the efficiency of the agricultural food sector has made a major contribution to this goal and will continue to do so indefinitely. I do not concur that any absolute goal of affluence can be established. This and the short shrift of other societal goals is a major weakness of the paper. Reference to the "man-on-the-moon" and "auto mileage" as goals are purely transitory and mundane in character.

Economic and Other Social Research

The economics profession is to be faulted for failure to elucidate clearly the contributions of economic research to the food system. Organization and management are certainly vital to an efficient and viable food system. Inadequate organization and management are reflected in cycles and other evidence of over-under production contributing to inefficiencies and misallocation of resources, to name a few. However, in the research planning and budgeting processes, these kinds of constraints are seldom addressed. The low level of federal support for economic research related to food and agriculture was clearly elucidated in the Phillips-Dalrymple paper. However, the role of federal and state performers was rather muddled. There is no clear delineation of state and local problems as opposed to national and international problems. Also, the allegation that economists have never developed a process for problem identification simply does not jive with the record. For example, a framework for marketing research with clearly delineated problem areas in a matrix format has existed for eighteen years (Southern Marketing Research Committee).

Although the role of the public sector and the private sector in PHT and marketing research was a key issue in the OTA assessment, it was not adequately treated in the paper. It should be clearly recognized that the potential for resource conservation and cost reduction in the post-harvest sector is enormous. Food science has the potential to reduce land and energy requirements by 60%–70%, and adjustments in this direction are inevitable.

Conclusion

The OTA assessment of agricultural-food research generated a lot of verbiage. It was well-organized and conducted. However,

whether or not the assessment provided any real direction to the U.S. Congress and to research management with respect to funding, priority-setting, role of participants, unnecessary duplication, program balance, and other issues is debatable. Some good points were made, but the paper did not provide direction for the future. Less but well-directed verbiage would perhaps be more effective and productive.

Research and the Family Farm: Implications for Agricultural Economics Research: Discussion

Eldon E. Weeks

Lee Day has done a courageous job, and as good a job as one can reasonably expect, in addressing this topic. The subject, inherently, is monstrously large; very ill-defined; and is a value-loaded, explicitly acknowledged cornerstone of U.S. farm policy. Day treated the subject wisely by addressing himself to a limited number of points—whether there is a slanting of experiment station research to the benefit of large farms, the economies of farm size, and agriculture and the community. Day said as much as could be said about these points within the constraints on the paper.

Because the discussant believes the above statements, this discussion will offer views of two additional dimensions that bear on both family farms and agricultural economics research. One of these dimensions consists of the consideration of basic definitional properties of family farms and a few of their implications for agricultural economic monitoring and research. The other is an expression of concern on my part over the apparent neglect, by economists, of activities involving the development and selection of advanced new biological/technological management systems in agriculture.

The Family Farm

According to the 1974 Census of Agriculture, 89.5% of all farms with sales of $2,500 or over were operated by individuals or families. These farms contain 74.9% of the land in farms with sales of $2,500 or over. Partnerships accounted for 8.6% of the farms and 13.7% of the land in farms. Thus, 98.1% of the farms, including 88.6% of the land in farms with sales of $2,500 or over, are operated by unincorporated farming institutions with proprietorships dominant.

The Standard Industrial Classification (SIC) Manual and the 1974 Census of Agriculture define farms as business establishments. With reference to the above data, agricultural enterprises are dominated by the operation of farms (business sector of the economy) by unincorporated households (households and institutions sector). Unless a farm is a single-establishment business enterprise operated by an incorporated operator, it is not a firm. This means that, in most instances, financial management, investment, and resource use decision making cannot be interpreted as self-contained functions within farm business establishments. Inputs are committed to farming operations, outputs accrue, and a residual of net factor earnings is available for transfer to the income accounts of farming institutions, 98.1% of whom are unincorporated operators. Of these, 69% receive income from off-farm sources.

The main impact of the above reduces to the proposition that, in the great majority of cases, the objectives guiding farm investments and activities are those of households rather than those of farm firms. Interpretation of the financial vitality of agricultural industry is directly dependent on the financial viability of the operator and his family, whose objectives related to farm investments and operations are members of a set of family objectives and aspirations. Thus, the size of current incomes from farm and off-farm sources may not be sufficient information to indicate financial status and progress, either of agriculture or of farm families, in terms of the combined perspectives of financial viability and well-being.

I wonder if it is not time to reexamine the

Eldon E. Weeks is a program analyst with the Cooperative State Research Service, U.S. Department of Agriculture.

The views expressed in this discussion are the author's and do not necessarily reflect those of the Cooperative State Research Service or the USDA.

kinds of definitional assumptions we make in modeling farming operations. And I wonder if we should again explore and identify relevant elements of the expected bottom lines motivating farm operator family behavior in relation to potential participation in such public policies as those concerned with farm production, resource conservation, environmental protection, food safety, etc. Also, I wonder if we cound not stand a catch-up effort in research on part-time farming, with emphasis on the economic behavior of part-time farm operator families. If we were to begin to delve into this subject, it is just possible we would discover that there is a lot we do not understand about that which we think we know.

Management Systems

It seems to me that there is an increasing tendency among agricultural scientists to adopt management systems orientations as frameworks for the design of biological/technological research and development programs. Examples of these are found in integrated pest management, integrated reproduction management, and several more related to crop and livestock systems management and other areas.

It would seem that economists and other behavioral scientists could be active participants in planning the design and delivery of research and development programs in these complex management systems areas for assurance that the bottom line objectives of family farm operators are considered. Often we see research program (project) goals stated, for example, in terms of such intermediate stages of impact as yield increase, just as if a number of other good things are bound to follow. We all suspect that circumstances of perspective and timing may affect the "goodness" of many of the things that might ultimately follow.

Even while the social and behavioral sciences are presently experiencing a belt-tightening era, it is possible that practitioners of research in these areas may find it fruitful to consider adding to their agendas some activities in needs assessments for research programs in the food and agricultural system. It may even be fair to propose that farm operator families in differing typical situations be considered among the major stakeholders in evaluating the research program alternatives.

Above all, it appears to me that farm operators are being asked to evaluate more and more increasingly complex technological and biological systems alternatives. One has to wonder how they can evaluate and integrate all the relevant practices that are urged upon them. Economic researchers could, again, commit serious attention to the evaluation of new biological/technological information and to the selection of management systems from the situational perspectives of farm operators.

Women in Agricultural Economics
(Sylvia Lane, University of California, Davis, Presiding)

The Conduct of the Survey on the Opportunities for and Status of Women in Agricultural Economics

Ardelle A. Lundeen and Annette L. Clauson

At its July 1980 meeting, the Executive Board of the American Agricultural Economics Association authorized formation of an ad hoc committee to investigate systematically the status, role, and opportunities for women in agricultural economics. A survey of females and males in the profession, including but not limited to members of AAEA, was undertaken. Because of the small number of women in agricultural economics (e.g., membership lists indicate that women comprise less than 5% of the AAEA), all women who could be identified in agricultural economics or related specialties were included in the survey. A sample of the much larger population of male economists was selected.

Questionnaire Development

The questionnaire was based on a similar design used by the Committee on the Status of Women in the Economics Profession (CSWEP) in 1974. Communications revealed that several items in the CSWEP 1974 survey were insignificant and therefore were left out of this survey. This survey was designed to make comparisons between male and female respondents, as well as to develop profiles in agricultural economics. The questionnaire was divided into five major parts.

Part 1 deals with the education and training of the respondents. This part covers when and why the respondents chose to become agricultural economists, as well as important positive role models that may have persuaded or dissuaded the respondents from entering the profession. Institutions attended, degrees received, and dates of degrees may be important when completing the profile of male and female respondents with respect to salary.

Part 2 covers work experience and career development of the respondents. Work history and no-work periods are key areas in part 2. The 1974 CSWEP survey indicated that wages, particularly the percentage of salary obtained from consulting fees, may show significant differences when profiling male and female respondents. Job mobility and types and numbers of publications are important areas dealt with in this part.

Part 3 covers the participation in the job market for agricultural economists since July 1979 and applies only to persons actively interviewing for jobs during that period. Questions on the type of prospective employer (university, business, or government) for each interview as well as the type of employer for a job accepted were included in this section. Comparisons of salary for jobs accepted, between male and female respondents and between types of prospective employers, are key areas of interest in this section. The number of interviews for each respondent is also a key item.

The effectiveness and problems of affirmative action during the hiring procedure are the emphasis of part 4. Possible problem areas dealt with in this section include female and male numbers in departments/divisions and in graduate programs, tenure, seniority, promotion, salary adjustments, and fringe benefits. Since the implementation of affirmative action, both males and females have indicated that they have encountered some problems in these areas.

Ardelle A. Lundeen and Annette L. Clauson are associate professor and research assistant, respectively, in the Department of Economics, South Dakota State University.

Research support for this study, provided by the Farm Foundation and by the ESS, U.S. Department of Agriculture, is gratefully acknowledged by the ad hoc Committee on the Status of Women in Agricultural Economics.

Part 5 deals with the personal background of the respondents. The specialties of the respondents may be significant when profiling male and female respondents. Family situation, including marital status, spouse's profession, number and age of children, is dealt with in this part.

The final questionnaire was designed to be administered to male and female agricultural economists, including graduate students; therefore only parts of the survey were completed by some respondents.

Sample Selection

Names of the female sample were obtained from several sources. The membership roster of the AAEA provided a starting point. Known women agricultural economists were asked to supply the names of other women in the profession. Women on the rosters of the Washington Women Economists (WWE) and CSWEP with relevant specialties also were included in the survey. A total of 540 persons made up the female sample (see table 1).

The male sample was selected from two sources. Each female respondent was asked to supply the name of a male of equal rank in her department or institution. To reduce bias in the selection process, the respondent was instructed to choose the male with the same rank or approximate level of job responsibility whose name appeared directly after (or before) hers in the alphabetical listing of agricultural economists at her institution or department. This matched-sampling procedure was intended to generate a group of males that would match as closely as possible the females under study.

Because only 84 names were obtained through the matched-sampling procedure, an additional 155 males were chosen randomly from the February 1981 list of paid-up AAEA members. The randomly chosen sample can be viewed to represent the male AAEA population more closely than the matched sample of male respondents. Identical questionnaires were sent to the females and males in the sample.

Table 1. Number in Sample and Response Rate for Surveys on Status of Women

Sample Group	No. in Sample	No. of Responses	Response Rate (%)
Female	540	159	29.4
Male	239	131	54.8
Matched	84	33	39
Random	155	98	63.2
Job search (both male & female)	233	122	52.4
Total	1,012	412	40.7

Early responses revealed that few persons had participated in the job market in the past two years and thus few persons had answered part 3 of the questionnaire, which involved job search activities. Since job search is an especially important component of the study, a separate questionnaire containing only part 3 of the original instrument, plus selected personal information, was developed and sent to persons who had accepted new positions within the past one and one-half years and to students nearing completion of degree work. Names of persons who had accepted new positions were obtained from AAEA newsletters from September 1979 to the present. Names of graduate students were obtained from rosters prepared by agricultural economics departments of universities and sent to prospective employers. Questionnaires were sent to 233 individuals in the job search sample.

Questionnaire Mailing and Response Rate

Questionnaires were mailed to approximately one-half of the female sample on 17 January 1981, with the remainder mailed a week later. Responses started to arrive in about two weeks.[1] The responses were generally slow in arriving, however, and after four weeks the response rate was only 21%. A reminder was sent to those who had not responded. Additional responses brought the return rate up to 29.4%. An additional 1.5% of the questionnaires were unusable because of incompleteness or wrong address. No further follow-up was undertaken for this group.

In view of the early indications of interest in the study by women and the fact that the results of the study have potentially important implications for them individually and more generally in the profession, the 29.4% re-

[1] The response rates and numbers cited in this paper reflect total responses in each category in each survey. Discrepancies between the numbers cited in this paper and the following three papers result from incomplete responses on some questionnaires and from different categories used by each analyst. For example, analysis may include all females, all males, matched sample of males and females, job search respondents, or some combination of these categories.

sponse rate is unexpectedly low. One possible explanation, however, is that women with specialties only peripheral to agricultural economics (e.g., Specialty Areas 420, 440, and 900–950) may not have identified closely with the profession.

The response to the 10 February 1981 mailing of the job search questionnaire was sufficient (a 52.4% rate) so that no follow-up mailings were made.

Questionnaires could not be sent to the male sample until the majority of female responses were received. Thus the mail questionnaires were not sent until 13 March 1981. Responses filtered in through 1 June 1981. One hundred and thirty-one responses were received, for a response rate of 54.8%. The response rate for the matched sample was 39% and for the random sample was 63.2%.

In this survey, as with most mail surveys, the possibility exists that the survey-respondents do not adequately represent the full range of members in the population. While the survey questions were factual, the objective of the project could have been viewed as controversial by some. A high response rate of individuals with strong pro or con feelings would be expected. For example, women who feel they have suffered discrimination and envisioned the study as a means to document this would likely have responded. On the other hand, females satisfied with their opportunities and/or who do not want to risk alienating male members of the profession may also have felt strong necessity to respond. Likewise, men who feel the study was anti-male or those particularly concerned with the status of women in the profession are more likely to have responded. Both males and females with neutral feelings, on the other hand, may have been less inclined to respond. While this raises the question of bias, time did not allow for the exploration of the possible nature of bias in the self-selection of respondents to the mailed questionnaires.

Coding and Analysis

The same coding structure was used for responses to all questionnaires to enable analysis not only by individual subgroups but for all subgroups combined. Selected personal information and job search activities were available from all 412 respondents. The remainder of the information from the longer questionnaire was available for 159 females and 131 males.

The male group was divided into two subgroups for analysis. Thirty-three of the male respondents comprised the matched-sample for comparison with their female counterparts. The remaining 98 male responses were from the randomly selected sample of AAEA members. This represents 2.97% of the total AAEA and may be used for analysis with the total female sample. The matched and random samples of males cannot be combined to provide a larger sample if either "matched" or "random" is a prerequisite. However, for some general characteristics, combining the two groups provides a larger sample for analysis.

Responses were coded and put on tape at South Dakota State University and sent to committee members for analysis of separate sections to be used in their respective papers.

A Comparison of the Rank and Salary of Male and Female Agricultural Economists

Linda K. Lee

The Committee on Opportunities for and Status of Women in Agricultural Economics was established by the Executive Board of the American Agricultural Economics Association in July 1980. The charge to the committee was "to ascertain the opportunities, role, and status of women in agricultural economics."[1] Two important determinants of status within the profession are rank and salary. The objectives of this paper are, first, to develop a profile of women within the agricultural economics profession. The distribution of female agricultural economists by type of job, level of education, and among academics, tenure status, is analyzed along with data on salaries, experience, and research productivity. Second, the relative rank of women within the profession is explored by comparing profile data of male and female AAEA members. Finally, a model is developed to determine if significant salary differentials exist between men and women of comparable rank. Conclusions about the current status of women in agricultural economics are presented.

A Profile of Female Agricultural Economists

Data for this analysis were obtained from a survey of men and women within the profession (Lundeen and Clauson). In an attempt to survey all female agricultural economists, 540 women with a possible interest in agricultural economics were contacted by the committee. Responses to the survey as of 1 July 1981 totaled 159 women, 89 of whom are members of the AAEA. Data in table 1 illustrate the distribution of women by type of job, level of education, and academic tenure status, where applicable. Mean salaries, average years since the last degree, and average number of publications per year are calculated for each category.

Of the 125 women who listed an identifiable current job, approximately 50% are academics, 30% are employed by government (state or federal), and the remainder are working for business and nonprofit corporations. The mean annual salary for all women surveyed is $20,589. Highest average salaries are reported by women with a Ph.D. employed by government. The lowest salaries are earned by non-Ph.D. academics without tenure, many of whom may be graduate students on assistantships. For all academics, the average annual salary of $17,659 is less than the average earnings of both government and business employees. It should be recognized that the inclusion of graduate students in the academic category may bias these salary comparisons.

The female survey respondents averaged just under six years since receiving their last degree. Overall, academics had more years of experience than government or business employees. The average number of journal articles and papers published per year was also calculated. All women surveyed averaged slightly less than one publication each year since their last degree was received.

Comparison of Male and Female Agricultural Economists

Questionnaires were sent to 239 males most of whom were randomly selected from the 1981 AAEA membership list (Lundeen and Clauson). One hundred thirty-one men responded by 1 July 1981. Because of the sampling frame used, most of the men surveyed

were AAEA members, while only 56% of women surveyed were association members. Although the differences between AAEA women and all women surveyed appear slight, to ensure comparable groups the responses were stratified for 104 male respondents and 72 female respondents with AAEA memberships.[2] These data are reported in table 2. Type of job, level of education, and academic tenure status were tabulated in addition to mean salaries, average years since last degree, and average number of publications per year for each job category.

Academics

Of the respondents with academic jobs, 55% of the men were tenured, compared to 24% of the women. A higher proportion of women than men did not have a Ph.D.: 51% of the women compared to 14% of the men. The "not applicable" response to questions about tenure status may indicate that many non-Ph.D. women are graduate students on assistantships. Apparently a higher proportion of female graduate students responded to our survey than did male graduate students, probably due to sampling techniques and interest in the survey.

Mean salaries for academic men are more than $14,000 higher than for their female counterparts, a trend that is observed in almost every tenure and educational category. Men also have more post-degree experience than do women—about five years more on the average. There is also a slight tendency for men to have more publications than women on a per year basis.

Government

Approximately 58% of the men in the sample and 48% of the female AAEA members in government have a Ph.D. Men with a Ph.D., however, have twice the experience as measured by years since the last degree and average almost $9,000 more per year in salary than women with a Ph.D. Among government employees without a doctoral degree, the experience and salary differentials are similar. Women in government appear to publish more than men, perhaps indicating an administrative role for more of the men.

[2] Twenty-seven men and seventeen women were deleted from the analysis because information on their current jobs was incomplete.

Business and Other

The largest disparities in salary and experience are found in the business and other category. Men averaged 13.7 years of experience and $38,667 per year compared to 2.3 years of experience and $17,292 in salary for AAEA women. However, there were relatively few respondents in this category. Women in business, as did women in government, reported more publications than men on a per year basis, perhaps indicating fewer administrative responsibilities than men.

Summary

A major difference in employment patterns between men and women is the smaller percentage of women employed in academic jobs. While 63% of male agricultural economists in our sample are employed by universities and colleges, 51% of female AAEA members have academic employment. Correspondingly, a higher proportion of women are employed in state and federal government than are men.

Mean salaries of AAEA women are lower than mean salaries of the men sampled. The average salary for the 104 men with an identifiable current job is $33,534 compared to a mean salary of $20,417 for the 72 women for whom data were available. Part of this differential may be explained by the years of experience accumulated by men and women. Men averaged 12.1 years since their last degree received; AAEA women as a group averaged 5.5 years of experience. In addition to less experience, women have a lower level of education than men. Approximately 57% of the women do not have a Ph.D. compared to 27% of the men. Both men and women average approximately one publication per year.

Factors Contributing to Salary Differentials between Male and Female Agricultural Economists

The descriptive data in tables 1 and 2 do not allow a comparison of the salaries of men and women with equivalent backgrounds. Although mean salaries for women are lower than mean salaries for men within each category, it is difficult to determine the role of experience, productivity, and other variables in producing this salary differential.

Accordingly, a model was developed to test

[a] Information on type of job was not complete for 27 male and 17 female respondents. These data were not included in this table.

for salary differentials between male and female agricultural economists after accounting for education, experience, research productivity, and other variables. The dependent variable in this model is before-tax 1980 salary or 1980 net business income, including consulting fees. Independent variables hypothesized to determine the salary of agricultural economists were:

(*a*) educational background—with Ph.D. = 1, otherwise = 0;

(*b*) research productivity—(i) number of journal articles and professional papers, (ii) number of books published;

(*c*) experience—(i) years since the last degree was received, (ii) tenure (months) in present job;

(*d*) administrative duties—administrator = 1, otherwise = 0;

(*e*) employer an academic institution—academic = 1, otherwise = 0;

(*f*) career interruptions—number of times unemployed for 6 months or more;

(*g*) consulting—percentage of income derived from consulting; and

(*h*) sex—female = 1, male = 0.

The regression results for the sample of men and women who are members of the AAEA are reported in table 3. After omitting incomplete responses, 145 observations were analyzed. The coefficients of the variables measuring publications and consulting proved insignificant. The coefficient for sex was significant, however, indicating mean salaries for women are $3,769 lower than for men, after controlling for the effects of other variables. This salary differential is considerably less than the $13,000 differential reported in table 2, indicating about $9,000 of that differential can be accounted for by variables other than sex.

[a] Numbers in parentheses are *t*-values (absolute value).

It is possible that the significant salary differentials between men and women reported in table 3 relate to differences in job responsibilities not measured by the independent variables. As academics are a more homogenous group with respect to job descriptions than business or government agricultural economists, a separate regression equation was estimated to test for salary differentials between men and women in academia—the largest employer in the sample.[3] The results are reported in table 4. After omitting incomplete responses, 105 observations were available for analysis. The coefficients of books, career interruptions, and consulting proved insignificant. Again, after controlling for all other variables, academic women had a mean salary $3,038 lower than that of academic men. This suggests that although much of the salary differentials between academic men and women reported in table 2 are accounted for by explanatory variables other than sex, a significant salary differential between men and women in academia does exist.

Although mean salaries of men and women are significantly different after controlling for the independent variables in the model, it should be noted that there are other determinants of salary that are not accounted for in this analysis. For example, sex and regional location could be correlated in such a fashion as to bias the results, but this could not be determined in this study. Another important determinant of salary, quality of work, is not readily quantified and was not available from the survey data. Salary and advancement also can

[3] Because of the small sample size, all women academics, including non-AAEA members, were included in the model.

Table 4. Regression Results for Men and Women with Academic Employers

Variable	Estimated Coefficient

be accelerated by interpersonal skills and rapport with colleagues and administrators, another unmeasurable factor. To isolate completely the effects of sex on salary, all of these factors should be considered.

The significant salary differentials between men and women reported in the models could result from a number of factors. If women in general are less mobile than men, have fewer job alternatives, and/or are less successful salary negotiators than men; salary differentials could result. Because the reasons for significant salary differentials are difficult to determine, it is interesting to note the responses of men and women in the sample on this topic. In response to the question, "Do you think you are paid less or have a lower level job than you would if you were the opposite sex?", approximately 4% of the men and 22% of the women said yes. A sizeable minority of women perceive salary differentials to exist and believe these differentials to be sex-related.

Summary and Conclusions

The survey data analyzed in this paper suggest that female agricultural economists have not yet achieved a rank within the profession equivalent to male agricultural economists. Lower levels of education, a lack of experience, and fewer women academics may be contributing factors. Furthermore, significant salary differentials between men and women exist after accounting for education, experience, research productivity, and other variables. These conclusions are consistent with reports of the rank and salary of women in science and with data on the rank of women economists in academia (Bayer and Astin, Bailey).

The real issue may be the future advancement of women within the profession rather than their current professional status. Although the number of women in the profession is currently small, one encouraging signal is the increasing numbers of female graduate students in agricultural economics. Between 1974 and 1979 the number of women enrolled as full-time graduate students in doctorate departments more than doubled—from 155 to 352. During the same time period, male enrollment increased by only 12% from 1,452 to 1,625 (Vetter and Babco).

These data indicate young women are optimistic about a professional future in agricultural economics. If that optimism is justified, the number of women in the profession should continue to increase. Improvements in the rank and status of these women, however, will depend upon advancement equal to that of their male counterparts.

sponse was much less for female college faculty than for other sources of influence.

In the present survey, men almost always cited males as their most influential role models; most often cited were fathers and teachers. While women also cited fathers and teachers most often, more diversity existed in their responses. In particular, women listed female teachers more often than male teachers, and mothers appeared to exert significant influence. Women identified females as often as males as their most influential role models, while men almost never listed females.

Both sexes most often listed professors as the people who most encouraged a professional career; the greatest differences between male and female responses occurred for friends (more important for men) and professors and mothers (more important for women). Almost all men said that no one attempted to dissuade them from a professional career; while the majority of women concurred, women also reported a variety of dissuasive influences.

Academic Background

While men were more likely than women to rank in the upper 25% of their college graduating class, women were more likely to rank in the upper 2%. Men were somewhat more likely to have had statistics and advanced mathematics courses as undergraduates, but women were more likely to have taken calculus, economic principles, and advanced (general) economics. Men were more likely to have been agricultural economics majors as undergraduates, although, like women, many men also turned to graduate agricultural economics from other undergraduate majors. In general, then, women have had more background in general economics than men, while men's academic background has been more agriculturally oriented.

Contrary to what the literature on women's career paths indicates, women Ph.D. recipients were about as likely as men to have interrupted their Ph.D. study. This again may be partly because women agricultural economists are more likely than men to have never married and never to have had children (or at least to begin having children after the highest academic degree was completed); thus, home responsibilities of women and men may be roughly comparable. However, when women did interrupt their Ph.D. study, it was more likely to delay the dissertation and for more extended periods of time. Surprisingly, men were more likely than women to delay the dissertation because of home responsibilities, and women more likely to delay in order to gain job experience. Although women were less likely to receive assistantships and during Ph.D. coursework provided their own financial support somewhat more often, during the dissertation period they were more likely to rely on fellowship support and less likely to rely on working their way through. During both phases, women were less likely than men to receive aid from relatives as a major source of financial support.

Also contrary to popular opinion, women agricultural economists were more willing to move more than 100 miles to a job which offered higher pay than were men. The increased likelihood that female agricultural economists have never married may contribute to this result. Because for the majority of married couples, the man's career still takes priority, one would expect at best an equalization of mobility of men with predominantly single women. However, women were more likely than men to have moved in the past because of family preferences.

Both sexes were more likely to concentrate on agriculture and natural resources as primary professional specialties; of these, women were about evenly divided between agriculture and natural resources. However, women more frequently than men listed consumer economics as their primary specialty (nine of the thirteen 900-classifications were in 920, consumer economics) and less frequently listed economic growth and development and business.

Factors Which Affect Completion of a Ph.D. Degree

Based on the factors discussed above, a logit model was constructed and estimated to explain the decisions of women and men to pursue and complete a Ph.D. degree (table 2). First, the later in school the person made the choice of field, the more immediate the possibility of getting the Ph.D. and the more likely that it would be undertaken and completed. Second, the primary reasons for choice of field were considered; perhaps if one chose the field because of personal interest in it, one would continue as far as possible in its study; while if one chose it because of economic opportunity,

Table 2. Logit Determinants of Ph.D. Completion

one could find sufficient opportunity at the bachelor's or master's levels. The encouraging influences of father, mother, and teacher were discussed previously; also included in the model were the lack of any encouragement and the lack of any discouragement. Those of highest academic ability were hypothesized to be more likely to complete the Ph.D.; those never married were presumed to have been more free to concentrate on graduate study.

As expected, men and women responded differently to these factors; however, not all of the predicted effects held at the 10% level of significance. Most unexpected was the negative effect of never-married status. It appears that for both sexes, the married individuals are more likely to complete the Ph.D. For both sexes, the later in life the decision was made to enter agricultural economics, the more likely the Ph.D. completion. No effect of reasons for choice appeared for either sex. College academic rank (1 = highest, 5 = lowest) was a significant factor for men but not for women. Men and women responded oppositely to most encouraging (and discouraging) influences. Men responded favorably to encouragement from fathers and teachers, although they apparently needed some challenge against which to respond as seen from the negative effect of lack of discouragement. Mother's influence could not be analyzed for men because very few men listed mothers as the people who most encouraged their careers. Either women responded negatively to encouragement from fathers and teachers (and surprisingly, not at all to mothers) or, more likely, the professional careers women were encouraged to undertake did not require a Ph.D. The model explained Ph.D. completion better for men than for women.

Conclusions

Women agricultural economists do differ from their male counterparts primarily in family situation and professional motivation. They are more likely to have never married, or at the least to have completed academic preparation before turning to child-rearing. When married, they are more likely to have married men of equal or higher educational background and income, and to possess a Ph.D. degree, but yet at the same time they appear to have largely resolved problems of career mobility. They are likely to be older than the males, on the whole (partly because of greater numbers of returning women students), and to have been more greatly influenced by female role models. Although they tend to have had a more general-economics-oriented academic background than the men, they presently specialize to no lesser extent in agriculture and natural resources. In keeping with the academic stereotype, however, they do choose human-oriented specialties more often than business-oriented specialties, while for men the reverse is true. The distinctive career motivation among women agricultural economists is intellectual interest, as compared with greater emphasis by men on market considerations. It will be interesting to see if these

patterns continue over time as women's participation in agricultural economics increases and whether the character of agricultural economics research output changes as a result.

Evidence on Barriers to the Parallel Advancement of Male and Female Agricultural Economists

Sylvia Lane

Barriers to parallel advancement of male and female economists and managers (but not agricultural economists) have been studied in some detail (Reagan, Strober, Epstein, Gordon and Strober). Reagan wrote, "On the supply side, barriers to full career development for women are likely to be those common to all professional occupations plus the effect of women's perceptions of the intensity of the demand-side barriers of the particular profession (i.e., any lack of support of male colleagues, professional isolation and lack of access to information network, or employers' lack of perception of the women's career potential). One group of supply-side barriers includes presence of children, husband's unfavorable attitudes, guilt feelings of women related to a high sense of responsibility for monitoring consumption at home, and poor earlier education choices based on limited perception of career possibilities. In addition, the two probably most important barriers are geographic mobility or immobility, related to demands of family, and lack of the on-the-job training caused by either gaps in the women's career patterns or diminished opportunities for investment in human capital for women who are working" (Reagan, p. 100).

Gordon and Strober emphasized "recruitment, hiring and promotion policies" (p. 158) (demand-side barriers common to all professional occupations), and Sutherland found women had lower professional aspirations (supply side) (pp. 774, 794).

Sylvia Lane is a professor, Department of Agricultural Economics, University of California, Davis, and an economist on the Giannini Foundation.

Giannini Publication No. 633.

A debt of gratitude is owed to graduate research assistants Bruce Guidici and Thomas MacLean and computer programmer, Christi Bengard, and to professors Barbara Zoloth and John Kushman of the Department of Agricultural Economics of the University of California, Davis; but the responsibility for what is written herein remains the author's.

The three highest barriers to career development cited by women with doctorates studied by Astin were "getting adequate domestic help" (supply side), "employer discrimination" (demand side) and "husband's mobility" (supply side) (p. 150).

Epstein lists (*a*) the American image of the female role and its concomitant attitudes and behavior which are often inappropriate in the professional world (which when internalized is a supply-side barrier); (*b*) simply enjoying one's work often not being perceived as an adequate justification for a woman working; (*c*) the lesser parental investment in education for young women in many cases because it has a lower present value; (*d*) the lack of role models for professional women; (*e*) societal expectations concerning appropriate occupations for women and pressure on women to think in terms of contingency careers instead of careers as their prime occupational objective; and (*f*) the tendency of women to choose typically female professions (Epstein, chaps. 1, 2). The listed categories are all supply-side barriers. They are not all mutually exclusive, and the list is not all-inclusive.

Irrespective of the factors involved, the lack of parallel advancement in occupational categories similar to that of agricultural economists has been documented. Reagan found a $2,400 difference in pay between the "typical" Ph.D. woman economist and her male counterpart seven years after the woman economist received her Ph.D. (p. 101). Johnson and Stafford, studying female academics, found "(1) beginning salaries for females are not substantially less than for male academics; and (2) the rate at which salaries increase with years since the Ph.D. . . . is much greater for male than for female academics" (p. 203). After twelve years of potential experience, women in their sample earned 23% less than the men (p. 203). Salaries of

female academics are averred to decline relative to those of male academics with years since receipt of the Ph.D. up to age 45 (p. 205). The important hypotheses explaining the differentials were both the division of labor/acquired skill hypothesis (women drop out of the labor force, primarily to raise children more often than men and do not acquire as much on-the-job training) and discrimination (pp. 216–17).

Human capital theorists posit time out of the labor market reduces the accrued human capital stock because of a gap in the process of appreciation and because of capital depreciation. Discontinuities were found to be greater for married than for single women (Mincer and Polachek). Huttner found the number of breaks in paid employment rather than time away from paid work to be inversely associated with earning levels, and Jusenius suggested women in high-skill occupations suffered the highest penalties (Kalsare, p. 663).

Reagan, from her analysis of the data from the 1974–75 survey of economists, suggested that the discrepancy between salaries for equivalent male and female economists was due to women accepting lower wages than men if their geographic mobility was restricted because of their husband's employment or if they wanted to work close to home because of children.

In this analysis, the hypotheses to be tested, stated in the null form, were that (*a*) attitudes, human capital, and mobility did not result in salary differences between female and male agricultural economists holding equivalent positions, and (*b*) barriers to parallel advancement were not falling and therefore salary differences for male and female agricultural economists holding equivalent positions, controlling for years out of school, should be the same for younger and for older women.

Methodology

Data used was from the Survey of Women in Agricultural Economics conducted in 1981 (Lundeen). First, frequencies were compiled for the occurrences of the barriers studied for a sample of 282 women in the surveyed population for whom there were complete records. One hundred eighty-four, designated as "younger women," had completed the requirements for their highest degree in 1971 or thereafter. Ninety-eight, designated "older women," were awarded their highest degree prior to 1971. Second, data for 21 pairs of "matched" male and female agricultural economists were used in a multiple regression analysis to explain salary differences. In all, there were 33 "matched" pairs in the data set, i.e., pairs of male and female economists working for the same firm or institution. Women had designated the man in the same department and/or position with equal rank whose name appeared next to their names alphabetically on the department list or employment roster. However, data needed for the analysis was incomplete for 12 of the pairs and, therefore, they were excluded from the regression analysis.

The model estimated was

$$D = f(A_s, A_d, C, M),$$

where D is the difference in salary between a woman who is an agricultural economist and a man in the equivalent position divided by the years since each received her/his highest degree, A_s is attitudes that have their effect on the supply of women who are agricultural economists, A_d is attitudes that have their effect on the demand for women who are agricultural economists, C is differences in human capital, and M is differences in mobility. A_s, in the estimated equation, was a series of eight variables. They were:

(*a*) if people tried to dissuade female respondents from pursuing a professional career;

(*b*) the need to devote a large amount of time to administer consumption;

(*c*) spouse's negative attitude toward the female agricultural economist's working;

(*d*) relatives' negative attitudes toward the female agricultural economist's working;

(*e*) lack of appropriate role models;

(*f*) social or professional isolation on the job;

(*g*) the number of times the respondent left a job she liked and moved because her spouse or another family member needed to live in another area; and

(*h*) other barriers which included (in their own words) lack of direction in college, lack of support from faculty when a student, inadequate financial support during graduate work, personal reluctance to call self economist and work with them, nonacceptance of women in field, lack of worthwhile work in field, inability to fit into system in place of work, no mentor, no referral/buddy system for women, work in

a chauvinistic company, difficulty about learning about available options, colleagues' sexist attitudes, personal obligations, nationality/cultural obstacles, and "political repression." This is not a complete list.

A_d in the estimated equation was a series of three variables:

(*a*) employers' lack of perception of female respondents' professional potentialities;

(*b*) employers' expressing a preference for hiring a male rather than a female agricultural economist; and

(*c*) questions related to the spouse and/or domestic situation appearing to be a disproportionately important consideration in the minds of potential employers.

Data used for the variable pertaining to less investment in human capital, *C*, was compiled from the number of six-month gaps in the work history of the women who responded in the survey.

To gather data concerning mobility, *M*, a question was included in the questionnaire asking if the respondent was willing to move to a better-paying, more responsible position 100 or more miles from her/his present location within the next two years.

These, except for family moves which were correlated with the number of six-month gaps, were the independent variables in the final regressions, which were estimated using ordinary least squares.

There probably are simultaneities and interactions among the independent variables. For younger women there were positive correlation coefficients over .6 for problems with consumption management and the number of six-month gaps in the work history. This was also true for the spouse's negative attitude and the reporting of having encountered other barriers. This could well be due partially to a psychological interaction.

Findings

As indicated in table 1, 53.5% of the 282 women who responded to this question indicated they had been dissuaded from pursuing their professional careers. Of the female agricultural economists responding 53.2% found the need to devote a large amount of time to administer consumption to be a problem. Her spouse's negative attitude toward her working was a problem for 52.8% of the respondents. Relatives' negative attitudes were a problem for 53.2% of the respondents. The lack of role models was a problem for 53.9%; isolation on the job for 52.8%; family related moves for 8.9%, and other barriers for 14.2%.

As for the demand-side barriers, 54.3% of the women reported the employer's lack of perception of their potentialities to be a problem; 20.9% reported their employers preferred to hire male economists, and 95.7% reported having been asked a disproportionate number of questions related to spouse and/or domestic situations during interviews, and that such questions appeared to be important considerations in the mind of potential employers.

Eleven percent reported there had been gaps in their work history and 32.3% reported they were willing to move more than 100 miles within the next two years to a job with higher pay and greater responsibility.

That over half were dissuaded was perhaps not unexpected. That consumption management was a problem for over half was also not surprising.

The fact that the female economists' domestic situations appeared an important consideration in the mind of potential employers according to over 95% of the women reporting is revealing. The almost one-third of the female economists reporting who are willing to move within the next two years to a job 100 miles or more away from their present job if it had more responsibility and higher pay was a higher proportion than expected.

Among the 130 male economists who responded to this same question, 39.2% reported they were willing to move. There was a statistically significant difference between male and female agricultural economists in this regard. The males were more mobile.

Actually, being married, in itself, constitutes a barrier interrelated with consumption management, gaps in work history, and spouse's negative attitude. Of the 62 women surveyed who reported consumption management to be a problem, 72.6% were married. Of the 55 women who reported they were single (never married) 78% reported consumption management was not a problem, as opposed to 40% of the 75 women reporting being currently married. Married women also had more gaps in their work history. None of the women who were not currently married (separated, divorced, or never married) reported having more than three gaps, but 10% of the 75 married women did. Forty-four percent of the married women had gaps in their work history as opposed to 33% of the single women.

Table 1. Evidence of Barriers to Parallel Advancement of Male and Female Agricultural Economists

Gaps in work history	7.6	17.3	11.0
	(2.2)	(5.3)	(2.4)
Mobility			
Willingness to move to job with more responsibility[c]	32.6	31.6	32.3
	(3.5)	(4.7)	(2.8)

[a] Percentage of women surveyed reporting this as a problem.
[b] Standard errors in parentheses.
[c] Only variable compared to males; difference between males and females significantly different above 95% level.

When comparisons were made between the women who had completed work for their highest degree ten years or more before the survey and those who had completed the work for their highest degree within the last ten years, some interesting differences became apparent (table 1). A higher percentage of the older women had encountered all of the listed supply-side barriers. The differences between the younger and older women were all statistically significant.

As to the demand-side barriers a higher proportion of older women reported their employers lacked perception of their potential. A lower percentage of older women reported their employers preferred hiring male economists or had a disproportionate interest in their family affairs. Older women had more gaps in their work histories, as expected. They had more time to accumulate them. The older women were somewhat less willing to move than the younger women, and that, too, was expected. This was also true of older versus younger men. Every one of the differences in the recorded percentages for the demand-side barriers between the older and younger women was statistically significant.

The mean difference in salary per year since they had acquired their highest degrees between the younger women in the sample and their male counterparts (for the 11 cases in the matched pairs) was $311.60 per year. The female economists earned less. The mean difference in salary per year since the acquisition of the highest degree for the older women in the matched pairs and their male counterparts was $59.38. The women earned more. The difference between the younger and older women

was statistically significant at the 95% level. For the 21 matched pairs, the mean difference per year was $134.94, with the men earning more.

The independent variables that were statistically significant in explaining the salary discrepancy for the 21 women in the matched-pair regression equation were (table 2) the spouse's negative attitude toward the female economist's working (at the 90% level); relatives' negative attitudes (at the 90% level); lack of role models; the employer's lack of perception of the female agricultural economist's potential; the employer's undue interest in family affairs during the female economist's interview; and the number of gaps in the female agricultural economist's work history (the latter four all being significant at the 95% level or above).

[c] Significant at 90% level.

Summary and Conclusions

The women questioned, who returned questionnaires in the 1981 survey of agricultural economists, had, for the most part, been dissuaded from becoming agricultural economists, found they had problems with consumption management, had spouses with negative attitudes toward their working, had relatives with negative attitudes toward their working, lacked role models, found they were professionally or socially isolated on the job, felt that they had employers who lacked perception of their potential, and had been questioned excessively about family affairs during interviews. Both the supply-side barriers and the demand-side barriers existed for a majority of these women. For the younger women, they undoubtedly contributed to the salary discrepancy between the women and their male counterparts, even though the younger women had fewer gaps in their work history. In the case of the older women, the discrepancy was positive. Those in the sample of "matched pairs" earned more than their male counterparts. But the sample was very small (there were 11 "younger" and 10 "older" women).

Statistically significantly higher percentages of older women encountered each of the supply-side barriers, leading to the conclusion that these barriers may no longer be as pervasive as they were. Concomitantly, statistically higher percentages of older women reported their employers lacked a proper perception of their potential, implying more employers may be perceiving female agricultural economists' potentials for achievement similarly to the economists' own perceptions (recognizing their capabilities). A statistically significantly lower percentage of older women, however, reported their employers preferred hiring male economists, which may indicate their employers' lack of bias when they were first hired or that they have proven women can be capable agricultural economists. The fact that the percentage for this barrier is as low as it is overall, (20.9%) is encouraging. The high percentage of the women surveyed who reported employers having an undue interest in family affairs during interviews (and this was statistically significantly higher for the younger women)

indicates women have yet to be treated equally with men during the interview process.

The statistically significantly higher percentage of older women reporting gaps in their work history probably reflects the milieu during the period of their careers. Many were working during the 1950s when the accepted norm for a woman was to be primarily home-centered, and this norm was then a more formidable supply-side barrier than it has been during the last 20 years (Korbin). That this percentage is as low as it is (17.3%) for older women and considerably lower for younger women (7.6%) indicates female agricultural economists tend to have strong career commitments. The fact that 32.3% of the women surveyed reported they were willing to move to a position paying more, with more responsibility, over 100 miles away from their present location dispels the notion that female agricultural economists are far less mobile than male agricultural economists. There is a statistically significant difference between the two (39.2% of the men were willing to move) but the difference is not that appreciable. Not surprisingly, the younger agricultural economists were more mobile than the older ones. And single women, who had fewer problems with consumption management, fewer gaps in their work history, and no spouses with negative attitudes toward their working, were more mobile.

Of the variables that were significant in the regression, three were supply-side variables: the spouse's negative attitude toward the female agricultural economist's working, relatives' negative attitudes, and the lack of role models. Two were demand-side variables: the employer's lack of perception of the female agricultural economist's potential and the employer's undue interest in family affairs during female economist's interviews (indicative of the employer's thinking). One, the number of gaps in the female agricultural economist's work history, would suggest a lesser acquisition of human capital, which would tend to result in salary levels lower than they might otherwise be.

The two significant variables that were unexpectedly associated with less, rather than more, discrepancy in salaries were relatives' negative attitudes and the employer's asking an undue number of questions about family affairs during the interview. The first may simply not be very important to the women. The second may be rational on the part of the employer assessing the commitment of younger women, but it is discriminatory and illegal. Its apparently not resulting in a greater salary discrepancy is an interesting finding.

The evidence, although in the case of the regression results it is only suggestive because of the small size of the sample, indicates that attitudes of both the males and the females and the difference in human capital do result in differences in salaries per year since completion of the requirements for the highest degree. The main impact of these factors is on younger female agricultural economists. Married female agricultural economists have more barriers to advancement than single female agricultural economists. But barriers are falling. Fewer younger female agricultural economists report encountering the "barrier indicators" considered in this analysis. Finis Welch's thesis may be correct. Each cohort in a minority group tends to encounter fewer barriers than the one preceding it, but it would seem the older women in the matched sample of female and male agricultural economists advanced faster than the males despite the barriers. The positive discrepancy for the older women could be accounted for by the presumption that Zoloth suggested: the older women had to be outstanding to overcome the higher barriers they faced. Kushman suggested they may have benefited from their scarcity in light of affirmative action pressures and their proven track records. In conclusion, there appear to be different supply and demand curves not only for male and female agricultural economists but for younger and older women among the female agricultural economists.

Abstracts

Symposia

Perceptions, Attitudes, and Risk: Overlooked Variables in Formulating Public Policy on Soil Conservation and Water Quality. Lee A. Christensen, presiding (ERS/University of Georgia), Peter Nowak (Iowa State University), Webb Smathers (University of Georgia), John Miranowski (Iowa State University), and Pierre Crosson (Resources for the Future), David Ervin (University of Missouri), and Wesley Musser (University of Georgia).

Nowak contrasted the traditionally held belief that wealthier farmers are more risk-prone and therefore more likely to adopt innovations with Cancian's thesis that the lower income groups are more receptive to adoption in the early stages of the diffusion process. He found Cancian's thesis to hold in the adoption of reduced-tillage systems. The risk-taking orientation associated with the early adoption of an innovation usually associated with higher income groups is diminished by uncertainty and limited information.

Miranowski discussed the inadequacies of budget analyses and linear programming models in representing the decision-making processes of farmers. These techniques generally ignore risk attitudes and human capital characteristics. Iowa farmers' perceptions of the yield impacts of various tillage technologies were found to be consistent with research evidence, but there is great variation in their risk attitudes.

Smathers addressed the disparity between actual and perceived attitudes of farmers toward conservation and water quality practices. Conventional wisdom holds that there is a weak private incentive to invest in soil conservation and water quality improvement practices. However, Georgia farmers were found willing to adopt technologies and management systems which would reduce input use and risk.

Crosson addressed the divergent interests of farmers and society on soil conservation and water quality. Farmers will not be nearly as sensitive to the off-farm damages of erosion as the public. Thus, where these damages exist there is a clear case for public intervention to reduce the damages. The argument for societal intervention for preservation of soil productivity is less convincing.

Issues in U.S./Soviet Bloc Agricultural Trade in the Eighties. James Jones, presiding (University of Idaho); David Schoonover (FAS USDA); Bob Jones (Purdue University); Steven Schmidt (University of Illinois); Dennis Conley (University of Illinois); and Robbin Johnson (Cargill).

Discussants in the symposium reported on research dealing with various facets of U.S./Soviet bloc grain-marketing arrangements and trade relations under auspices of the NC-139 regional research project.

Prospects of Soviet agricultural import requirements in the 1980s were surveyed. It was observed that the Soviets likely will remain an important buyer of U.S. grain products for the foreseeable future. The bilateral grain agreement between the United States and the Soviets was appraised in terms of its historical performance. Its value in facilitating acquisition of information from the Soviets of their import intentions was noted. Possible firm-level strategies of dealing with Soviet bloc purchasers through countertrade, technical assistance, and other arrangements were raised. How successfully the Soviet bloc economies deal with their shortages of foreign exchange, and the course that political relations take with the West were noted to be overriding considerations in shaping agricultural trade prospects.

Economic Statistics for Agriculture: Current Directions, Changes, and Concerns. Richard Perrin, presiding (North Carolina State University), William Kibler (SRS USDA), Shirley Kalleck (Bureau of the Census), Gaylord Worden and John Berry (Office of Federal Statistical Policy and Standards), Glenn Nelson (University of Minnesota), Bruce Gardner (University of Maryland), and James Bonnen (Michigan State University).

Kibler reported on the current probability survey approach used by SRS, including a description of sampling frames and sampling procedures for crop and livestock reports, and he described changes in the offing. Kalleck discussed the changes in enumeration procedures between the 1974 and 1978 agriculture censuses and listed some changes to be made in the 1982 census. She then discussed census concerns for the future, especially the difficulties in describing farm structure changes as farm-nonfarm linkages continue to change. Berry and Worden described sources of pressure on census and USDA statistical operations, including federal budget restrictions and mandated reductions in respondent burden, and urged the profession to organize so as to influence the changes that will occur.

Nelson reviewed in some detail the changes in statistics made since the Price Spread Task Force report and concluded that the report was used in a constructive manner and that it had a significant impact. Gardner reviewed recommendations of the Task Force on Economic Indicators and concluded that ERS had responded wisely, but went on to list remaining problems in the accuracy of some series and the meaning of some others.

Bonnen pointed out several factors which have increased the value of economic statistics (deregu-

lation, formula funding, farmer information systems) and urged the Economic Statistics Committee to attempt a careful description of remaining data problems. The papers prepared for this symposium will be duplicated and made available through the organizers.

Survey of Annual Outlook Information: 1981. John Ferris, presiding (Michigan State University), Gene Futrell (Iowa State University), George Hoffman (ESS USDA), Everett Nichols (North Carolina State University), Leonard Haverkamp (Wilson and Company), James Cornelius (Oregon State University), and Dean Chen (Wharton EFA).

The symposium was organized around the results of the fourth annual survey of AAEA members' forecasts of selected agricultural and economic data. A general summary of the 1981 survey results was presented by Gene Futrell. As with previous surveys, there did not appear to be any consistent forecast differences associated with the respondents' institutional affiliation, degree of outlook responsibility, or the extent to which formal forecasting models were used. Hoffman presented the detailed survey results on forecasts of general economic and general agricultural data and expressed his view on the likely values for the various data. Similarly, survey results and comments on crops were presented by Nichols and on livestock and poultry by Haverkamp. This was followed by general discussion.

Cornelius presented an analysis of the results of the three previous AAEA surveys of annual outlook information. Forecasting performance was evaluated for slaughter cattle, feeder cattle, hogs, corn, soybeans, and wheat. Near-term forecasts (for the current year) have been more accurate than far-term forecasts (for the following year). Forecast accuracy has also varied among commodities. Chen discussed the sources of forecasting errors and procedures for decomposition of forecast error. He suggested that more consideration be given to the identification and measurement of the reasons for error in outlook forecasts.

New Dimensions in Teaching Agribusiness Management, Farm Management, and Agricultural Policy. Duane G. Harris, presiding (Iowa State University), William D. Dobson (University of Wisconsin), Carl L. Pherson (California State University-Fresno), and R. G. F. Spitze (University of Illinois).

This symposium discussed future challenges in teaching courses in agricultural economics and agricultural business. Brief presentations were made by Dobson on agribusiness management, Pherson on farm management, and Spitze on agricultural policy. Then the audience divided into separate discussion groups for each of the subject matter areas, to share teaching ideas.

Dobson emphasized that good teaching in agribusiness management is highly labor intensive. Effective use of case studies can greatly enhance student learning, but such exercises require a substantial commitment of faculty time, especially as class sizes continue to increase.

Pherson suggested that future challenges in teaching farm management include meeting a growing need for developing student expertise in the areas of labor management, credit management, tax management, and government regulation. He also argued that risk management and intergenerational transfers of farm ownership and control need more attention.

Spitze stressed that three overall strategy issues arise in the teaching of agricultural and food policy—serving various levels of student academic maturity, selecting the subject matter content of our instruction, and developing an effective approach to teaching policy.

Modeling Agriculture in the 1980s. Marvin Duncan, presiding (Federal Reserve Bank of Kansas City); Dean W. Hughes (Federal Reserve Bank of Kansas City); John B. Penson, Jr. (Texas A&M University); and Hovav Talpaz (Texas A&M University).

This symposium examined three modeling efforts and the manner in which general economic and agricultural sector data are incorporated into these models. Womack's paper reports on the design and application of a sector econometric model that incorporates supply and demand interaction among agricultural commodities. Particular attention is devoted to incorporation of relevant international economic data into the model.

The Hughes-Penson paper outlines a general equilibrium model (GEM) and its application in valueing the incorporation of agriculture in a macroeconomic model. GEM captures the following important linkages with agriculture: producer-input supplier, farm output-retail food demand, balance of trade-exchange rates, government sector, and credit markets.

The Talpaz-Penson paper addresses the design and application of general equilibrium optimization models emphasizing agriculture. The models discussed utilize a quadratic input-output methodology, which relies on welfare economic theory, and are particularly useful for national and regional policy analysis.

The Implications for U.S. Agricultural Trade of Enlargement of the European Community and Future Developments in the Common Agricultural Policy. Stephen Magiera and John Dunmore, presiding (ERS USDA); Tim Josling (Stanford University); Gene Hasha, David Kelch, and Tham Truong (ERS USDA); Harold Riley (Michigan State University); Robert Thompson (Purdue University); and Alexander Sarris (University of California, Berkeley).

The newest EC enlargement must be viewed within

the context of the Community's current budgetary crisis. The common agricultural policy (CAP) is seriously threatened by the expense of mounting agricultural surpluses. Rather than a radical restructuring of the CAP, one is likely to see price restraint or restrictions on the quantities qualifying for CAP support, particularly milk products and cereals. The accession of important producers of Mediterranean products will exacerbate some of the CAP's problems and influence its evolution. Competition and budgetary problems will be heightened, particularly when Spanish and Greek olive oil come under the CAP.

The ability of the new countries to take full advantage of CAP regulations and aid depends on a number of factors—one of which is the formation of producer groups. In Spain, these groups are few in number and poorly organized in comparison to their EC counterparts.

EC tariff reductions on new members' fruits and vegetable exports will lead to a sizeable expansion of their sales to the EC. However, the enlargement impact will be small compared to overall trends in world trade. U.S. cotton exports could expand because of the abolition of Greek and Spanish tariffs and because of the greater restrictions imposed on EC textile imports negotiated under the new multifiber arrangement.

Enlargement could have a substantial impact on livestock production and feed demand in the new members. Corn and sorghum deficits, although continuing, will increase at a much slower pace. U.S. soybean exports will continue to expand because of the elimination of Spanish soybean tariffs.

Agricultural Transportation in Transition: Issues and Policy. Forrest Stegelin, presiding (University of Florida); Ken Casavant (Washington State University); Marc Johnson (North Carolina State University); Lowell Hill (University of Illinois at Champaign-Urbana); and Stephen Fuller (Texas A&M University).

The role of transportation is to facilitate agriculture and the consumer, not to reinvent the wheel. Agricultural transportation is characterized as an intermediate service (a total derived demand), playing a sensitive role in establishing the quality of competition among both firms and regions, and a geopolitical phenomenon (not just economic) having an enormous proportion of overhead in total cost. Traditional issues include the competition (or lack thereof) between modes, the stability and performance of exempt carriers, short-haul versus long-haul performance, and the cost economies associated with existing managerial expertise. Relatively new issues include the costs and availability of energy, truck weight and length restrictions, rail car shortages, intermodal arrangements, backhauls, highway user fees (cost responsibility by size), waterway user charges, locks and dams, seasonal rates, storage and export facilities, managerial opportunity costs and imperfect knowledge, and reregulation. Welfare theory and the recovery of public investment, potential regulation (inconvenience versus inefficiency), and deregulation are the likely issues and policies forthcoming in agricultural transportation.

Microcomputer Applications: Hardware, Software Documentation Professional Reward, and States' Activities. James M. McGrann, presiding (Texas A&M University), Gordon A. Rowe (University of California), Steven C. Griffin (Texas A&M University), and Ernest Bentley (Virginia Polytechnic Institute and State University).

This symposium discussed microcomputer hardware, operating system and language trends, program documentation and software evaluation, and professional evaluation and recognition for computer software development. Individual state activities were presented by participants.

Noncompatibility of microcomputer hardware, operating systems, and languages is a problem facing microcomputer users. Rowe stated that the CP/M operating system is increasingly accepted as an industry standard. Standards have been developed for the S-100 bus microcomputer systems but not for integrated systems like TRS-80, Pet, or Apple. Structured features for new versions of BASIC and standards to discourage incompatibilities to protect competitive positions of manufacturers can be expected.

Griffin discussed the problem of lack of user manuals and documentation of microcomputer software. Minimum requirements were specified for documentation and manuals. A check list is presented to facilitate software selection and evaluation for farmers and ranchers.

Bentley noted that agricultural economists have a new media to disseminate their research and educational programs through microcomputer software. Means to provide evaluation and peer review of software must be found to gain recognition by administrators for the professional activity in development of software. Bentley suggests a journal of agriculture software be developed.

Development and Application of Cooperative Theory and Measurement of Cooperative Performance. Randall E. Torgerson, presiding (ACS USDA), George Ladd (Iowa State University), Jeffrey Royer (ACS USDA), John Van Sickle (University of Florida), and Mahlon Lang (Purdue University).

Papers presented on cooperative theory were original approaches based on cooperative objectives. Ladd surveys past theoretical and empirical work in the context of cooperatives' objective functions and synthesizes one that recognizes both the interests of members on the farm and in the cooperative. In so doing, he advocates the use of mathematics to carry out informative institutional economics. In a

means-end hierarchy of goals, Ladd argues that a cooperative's highest-level objective is maximization of members' net revenue, or more precisely, maximization of present value of members' net revenue.

Royer presented a model for the short-run production and pricing decisions of cooperative associations. The model was compared graphically to earlier works by Phillips and by Helmberger and Hoos.

Van Sickle reviewed cooperatives' treatment under the various tax laws and presented a model of the financial structure of cooperative associations. This model essentially adopts that presented by Royer in developing a theory of cooperative financial structure.

Lang summarized results of comparative performance studies of cooperatives and noncooperative firms. The study found that cooperatives provide more marketwide and producer services than do noncooperative firms. They also provide farmers with a greater sense of control over their destinies and more market security. Aside from these factors, no dramatic difference in the performance of cooperatives and noncooperative firms were reported.

Economic Modeling Inputs to Pesticide Regulatory Decisions: Comparison of Alternative Models. Arnold L. Aspelin (Office of Pesticide Programs, U.S. Environmental Protection Agency) and Earl R. Swanson, presiding (University of Illinois), Klaus F. Alt (ESS USDA), Fred T. Arnold (Data Resources, Inc.), Glenn S. Collins (Texas A&M University), Dennis C. Cory (University of Arizona), Lewis Daugherty (University of Arizona), Earl O. Heady (Iowa State University), Wen-yuan Huang (ESS USDA), Roger A. Selley (University of Arizona), C. Robert Taylor (Montana State University), Sue Webb (Iowa State University), Edward Weiler (Office of Pesticide Programs, U.S. Environmental Protection Agency), and Thomas Yost (administrative law judge, U.S. Environmental Protection Agency).

Several months prior to the symposium, four different modelling groups were asked to estimate the economic impact of cancelling the registration of a hypothetical pesticide used on soybeans in twenty-five states. Results from four models were presented: (*a*) AGSIM, a regionalized econometric-simulation model developed by Collins and Taylor, (*b*) the NRED-CARD Hybrid model developed at Iowa State University, (*c*) the DRI (Data Resources, Inc.) econometric model of U.S. agriculture and the DRI macromodel of the U.S. economy, and (*d*) a simplified supply/demand model developed at the University of Arizona. Each of the four estimates of total average annual impact was divided into its impact on consumers and on producers. Although the estimates of total impact from three of the four analyses were remarkably similar, there were substantial differences among models in the allocation of the impacts between consumers and producers. In his comments on the results, Yost emphasized the importance of using basic economic logic and removing economic jargon from reports to be used as testimony in the regulatory process.

Industry, Government, and Academic Perspectives on Research Priorities in Agricultural Marketing. Clement E. Ward, presiding (Oklahoma State University), Timothy M. Hammonds (Food Marketing Institute), Allan B. Paul (ERS USDA), Richard G. Heifner (AMS USDA), and J. Bruce Bullock (Oklahoma State University).

Performance of the food-marketing system is being increasingly questioned. Symposium participants discussed the adequacy of agricultural marketing research in answering these questions.

Agricultural economists have become quantitative historians and are not addressing fundamental economic issues. Industry economists believe the *Journal* contributes to the image that agricultural economics research is irrelevant to the business community. Research focusing on increased productivity in the food distribution system is needed.

Government economists are faced with a broad array of problems. Research needs include intangible marketing functions. For example, research is needed on the proper role of government, e.g., cost-benefit analyses of government services and institutions and the optimal level of government to maintain competition.

Much of the agricultural marketing literature suggests our food-marketing system is inefficient. Relevant questions are whether a feasible alternative industry structure could provide more net consumer welfare without increasing resource use. More attention is needed conceptualizing how markets behave in a dynamic, uncertain environment.

Agricultural Economics in China. R. J. Hildreth, presiding (Farm Foundation), Reed Hertford (Ford Foundation), Peter Calkins (Iowa State University), Larry Connor (Michigan State University), Delane Welsch (University of Minnesota).

Agricultural economics in China is undergoing a rebirth. All teaching and research in agricultural economics ceased in China during the cultural revolution. In 1976, China's new leadership revived the profession to foster more effective management of agriculture.

The demand for agricultural economists appears large, relative to supply. The Agricultural Economics Society has a membership of about 1,000, which may also be a good estimate of the number of senior economists.

Plans call for doubling undergraduate enrollment by 1985 from the 2,600 now enrolled. Several agricultural colleges and universities have been desig-

nated key point schools and have priority in teaching staff, teaching materials, and students. Probably no more than 50 agricultural economists are presently receiving graduate education in China.

Possible AAEA activities to help reinvigorate agricultural economics in China, perhaps through a special committee, include: back-stop assistance for the Chinese Agricultural Economics Society; invite the Chinese to review AAEA's activities; make the exchanges between the U.S. and China in agricultural economics flow both directions; and provide publications to help rebuild agricultural economics libraries.

Embargoes Evaluated. Gary L. Seevers, presiding (Goldman, Sachs & Co.), Ted Rice (Continental Grain Company), Tim Josling (Stanford University), and Dale Hathaway (Consultants International).
The panel reviewed the consequences of four "embargoes": 1973, 1974, 1975, and 1980. The first three were based on actual or perceived short-supply situations; the fourth on political grounds. The first applied to all countries; the last three were directed primarily at the USSR.

Josling provided a classification system. The four embargoes would fall in at least three different categories.

Although each embargo has been unique, all share the following attributes: (*a*) Embargoes are disruptive and add uncertainty to all parties. (*b*) While the immediate result has been to depress U.S. grain prices, the impact on volume of world grain trade has been minimal because grain is fungible. (*c*) Longer-term adverse consequences may have been exaggerated, but one has been greater reluctance by importers to become overly dependent on the United States for supplies.

Most discussion was about the USSR embargo announced 8 January 1980. Hathaway said decisions to invoke embargoes have been taken without regard to or without examination of technical analysis of either their effectiveness or their domestic and international consequences. In brief, embargoes have been made for political rather than economic reasons.

Embargoes were considered undesirable. Ways to avoid short-supply embargoes were suggested. Nevertheless, panelists agree that embargoes were likely to occur again.

United States Agricultural Transformation and the State: Alternative Perspectives on Emerging Contradictions and the Continuing Crisis. Christopher Feise, presiding (King County, Washington, Cooperative Extension), David Holland (Washington State University), Phillip LeVeen (Public Interest Economics, West), Darrel McCleod (University of California, Berkeley), and Margaret Andrews (Rutgers University).
Three overlapping subject areas were given attention: (*a*) the role of the state and the problems it faces as it attempts to resolve the contradictions associated with the current stage of advanced capitalism; (*b*) interrelations between agricultural export policy, food price inflation, wages, and changes in real output; (*c*) the dynamics of agricultural structural change and the implications for changing class and political locations in the rural population.

One basic theme was that the "market-(export) oriented" approach to food policy, while fulfilling the promise of expanded markets and increased exchange earnings, has simultaneously resulted in the development of greatly increased food price instability. The role of food price changes in affecting industrial sector wages, industrial profits, rates of industrial productivity growth, and monetary and fiscal policy was discussed.

An additional major topic was the changing class location of the agricultural population emphasizing the implications for political alignment. It was argued that the main feature of U.S. agricultural structural change has been the decomposition of independent commodity production (family farming) into one of three major categories: wage laborer, part-time farmer, or capitalist farmer.

The social base for populist politics in rural areas is disappearing as capitalist farming increasingly dominates agriculture. Part-time farming, while occupying a contradictory class location, appears to be obscuring the contradictions of agricultural structural change.

Extension Programs That Work: Some Real World Examples. Gerald Campbell, presiding (University of Wisconsin, Madison), Richard Barrows (University of Wisconsin, Madison), Gerald Doeksen, and James Nelson (Oklahoma State University).
Barrows discussed his public policy education program on rural land use policy. He employed a variety of educational methodologies and materials in the different stages of problem identification, discussion of policy options, state and local government choice, and program implementation and review. His clientele included farmers, farm and environmental organizations, the Wisconsin State Senate and Assembly, the Wisconsin Department of Agriculture Trade and Consumer Protection, and other state agencies. Barrows and his students developed a research base on farmland preservation programs, and he worked closely with legislative enactment of the Farmland Preservation Program. Barrows was on part-time leave as the initial administrator of the program.

Doeksen and Nelson emphasized the importance of direct contact with clientele groups in problem identification. They emphasized that their 25% research appointments allowed them to generate the bulk of the needed research. Doeksen and Nelson reported on programs in community service, economic development impacts, and taxes. Primary

clientele groups were local governing boards and operations personnel for towns, counties, and special districts. Their program has produced well over 100 local community reports.

Local Government Service Provision in Nonmetropolitan Areas. Brady J. Deaton, presiding (Virginia Polytechnic Institute and State University), Paul Gessaman (University of Nebraska), Judith N. Collins (EDD ESS USDA), and Paul W. Barkley (Washington State University).
Each emphasized the need for rural communities to be understood as institutions by both researchers and decision makers. Gessaman charged that the profession has not sustained its commitment to community services research. He presented a model for minimizing the conceptual difficulties of output measurement and borrowed concepts from activity analysis to guide researchers.

Collins related trends in local government finances to changes in income, population, and debt of various size communities. Rural governments depend more heavily than urban areas on local property taxes and user charges. "Revenue effort" has recently declined in metropolitan areas and to an even greater extent in rural counties adjacent to SMSAs.

Barkley stressed the inherent conflicts among the concepts of efficiency, equity, and institutional reform as applied to community services. Attempts to base policy on these concepts may run counter to policies designed to promote a sense of "community" based on small-scale, geographic restrictions and local control.

The New Agricultural and Food Policy—Status Report. Robert G. F. Spitze, presiding (University of Illinois), Hazen F. Gale (U.S. Department of Treasury), Kenneth C. Clayton (ERS USDA), Wayne A. Boutwell (Staff Economist, Senator Cochrane), Harold D. Guither (University of Illinois), and Daryll E. Ray (Oklahoma State University).
New public agricultural and food policy is being developed to succeed the terminating Food and Agriculture Act of 1977. This follows the evolutionary path of price and income policy initiated in 1929. The new policy will be important to producers, consumers, traders, agribusinesses, and rural communities. This symposium provided an opportunity for agricultural economists to hear from policy workers close to the decision making but from different vantage points, about the issues, participants, and likely directions.

Gale stressed the high priority given to budgetary considerations in all policy decisions. Clayton concurred and expanded the theme about how the new budget process and "budgeteer" staffs had shifted the dialogue from program content to costs, perhaps to occur annually. Boutwell recounted similarities with past congressional hearings, counselled agricultural economists to be more active in policy, and identified problems for research.

Guither summarized the views of a sample of farmers in ten states, finding their preferences generally expressed in the new policy. Ray's evaluation of the primary future policy problems included finding instability issues becoming more intense and structural issues becoming dormant.

How Can the International Committee of AAEA Expand Its Service to the Agricultural Economics Profession? Darrell F. Fienup, presiding (Michigan State University), Arthur J. Coutu (North Carolina State University), James P. Houck (University of Minnesota), and Morris D. Whitaker (BIFAD and Utah State University).
The basic concern of this symposium focused on ways and means by which the AAEA International Committee can help strengthen the capabilities of the agricultural economics profession in development work. There is particular need to increase the participation of young U.S. professionals in international development research and training activities in both the U.S. and abroad.

One proposal would create a new discipline-oriented institutional structure that might be organized by the AAEA International Committee to serve as a contracting, granting, and implementing agency for international training, research, and overseas technical assistance. Projected benefits would derive from a more focused approach to development issues and more effective utilization of talents available. Constraints include long-term funding for a core budget and potential conflicts with existing institutions that employ internationally oriented agricultural economists.

The International Committee, as presently organized, should give greater support to communication and interaction among younger U.S. and LDC professionals. Seminars and workshops, like those sponsored under ADC/RTN, were considered an important activity for professional interaction. The need for more research opportunities in development, especially small grants for Ph.D. thesis research, was emphasized. Communication about existing sources of funds needs improvement. Establishment of better linkages with the International Research Centers, BIFAD, AID, ISEC, etc., should help to promote shared objectives as well as improve international opportunities for AAEA members.

Socioeconomic Factors Affecting Rural Land Use. Gerald Cole, presiding (University of Delaware), Greg White (University of Maine), Dale Colyer (West Virginia University), Bruce Lindsay (University of New Hampshire), and Nelson Bills (USDA ESS).
Discussion centered around the sampling procedure, methodology, and hypotheses tested for a survey of over 1,600 rural landowners in nine

Northeast states in 1979 and 1980. The central hypothesis of the study was that attitudes and views of growing numbers of nonfarm rural residents can significantly affect land-use policies and decisions.

White discussed sampling procedure and survey design. The sample was based on population growth and density by county in the northeastern states for the period 1970–76. The questionnaire was designed to obtain a socioeconomic profile of the owner/user, basic information about land ownership and use, and gathered responses on a range of attitudinal variables.

Colyer described the owner characteristics and reasons for owning land. Lindsay briefly summarized the empirical results of the study and related the results to existing land-use regulations in the northeastern states. Owners who do not expect land-use changes in the next five years represent the highest proportion in support of land-use regulations.

Bills compared the USDA national land-use survey results with those obtained in the Northeast and noted a high degree of similarity between the two studies for the Northeast region.

Selected Papers

Irrigation Policy and Practice (Harry Ayer, NRED ESS USDA/University of Arizona, presiding)

"Irrigation Scheduling in the Oklahoma Panhandle Using Stochastic Dominance Theory." (Thomas R. Harris and Harry P. Mapp, Jr., Oklahoma State University)
Irrigated production in the Oklahoma Panhandle has increased significantly during the past three decades. However, the source of groundwater is declining and the cost of fuel is increasing. Proposed irrigation technologies which use less water and fuel are evaluated by stochastic dominance analysis for possible adoption by irrigated producers.

"Economic Impacts from Regulating Groundwater Use." Dorothy A. Comer (University of Florida) and Raymond J. Supalla (University of Nebraska)
Groundwater mining has become a critical issue in several areas. This study uses a recursive linear program linked directly to a hydrologic model to evaluate how groundwater use regulations would impact on farm income in Nebraska. Findings indicate that it is possible to significantly extend aquifer life, without substantially reducing farm income at either the firm or the regional level.

"Optimal Groundwater Mining in the Ogallala Aquifer: Estimation of Economic Loss and Excessive Depletion Due to Commonality." Kun C. Lee, Cameron Short, Earl O. Heady (Iowa State University)
The optimal rates of intertemporal and within-group groundwater mining in the Ogallala Aquifer are estimated for the year 1985 to 2005. Economic losses and excessive depletion due to commonality and economic life of the aquifer are measured under alternative levels of energy and crop prices.

"Motivating Adoption of Best Management Practices: Implications for Cost Effectiveness." Donald G. Killingsworth and Scott C. Matulich (Washington State University)
The traditional cost effectiveness framework was broadened to incorporate some key motivations underlying the adoption of erosion control practices in irrigated agriculture. Selected financial factors were found to be important determinants of adoption. Failure to incorporate such factors promotes overestimation of cost effectiveness, improper ranking of BMPs, and ultimately faulty policy prescriptions.

Modelling (Larry Salathe, NWS ESS USDA, presiding)

"Modeling and Testing for Jointness in Agricultural Production." C. Richard Shumway and Rulon D. Pope (Texas A&M University), and Elizabeth K. Nash (University of California, Berkeley)
Allocatable fixed factors, e.g., land, must be added to the traditionally regarded causes of jointness in agriculture. Their presence also necessitates multiple-product systems for modeling product supply and factor demand. In other important ways, however, their analytical implications are very different from other causes of jointness.

"Use of Stochastic Simulation to Value Improved Crop Forecast Information." Duane L. Marquis (FAS USDA) and Daryll E. Ray (Oklahoma State University)
Consumer and producer surplus is used with the National Agricultural Policy Simulator (POLYSIM) to estimate the value of improved crop forecast information. For the three supply-demand scenarios evaluated—excess, tight, and fluctuating—the net domestic value of improved information is positive ($512 and $73 million) for the latter two situations.

"Tatonnement Modelling: A Variation to Linear Programming." Burton C. English, Cameron Short, and Earl O. Heady (Iowa State University)
An iterative solution incorporating demand equations and on national interregional linear programming model is explored. Conditions for stability are found and comparison of an iterative solution process and a fixed demand solution is made. The iterative process used in the analysis allows the model to adjust demand levels when the supply curve shifts as a result of increased production costs.

"Agricultural Price Expectations: An Erroneous, but Better, Approach to Measurement." Robert D. Weaver (Pennsylvania State University)
The subjective, market-level expectation of price is an unobservable which at best can be measured with error. The usefulness of the past and current cash prices and futures prices are considered. An errors-in-variables model of price expectations is introduced and applied in a model of U.S. aggregate soybean supply.

"Demand, Supply, and Price of Hardwood Lumber." William G. Luppold (U.S. Forest Service) and Joseph Havlicek, Jr. (Virginia Polytechnic Institute and State University)

A cobweb model with causal flow originating from the demand relationship is used to analyze the effects of exogenous variables on quantity and price of hardwood lumber. Wage rate, interest rates, stumpage price, lumber exports, and price of lumber demanders' output were the major factors influencing quantity and price.

Grain Policy (Edward W. Tyrchniewicz, University of Manitoba, presiding)

"Modeling Acreage Response in a Controlled but Uncertain Market." Robert G. Chambers (University of Maryland) and Richard E. Just (University of California, Berkeley)
A method is developed for modeling acreage response subject to acreage quotas is developed and applied to the case of wheat. The model assumes expected utility maximization and empirical analysis is based on the indirect expected utility function and limited dependent variable analysis.

"An Economic Analysis of the Effects of Commodity Program Options on the Financial Position of Representative Indiana Crop Farms." Mark A. Edelman, Marshall A. Martin, and Timothy G. Baker (Purdue University)
Financial positions of four Indiana crop farms were analyzed with an annualized LP model. Commodity programs that distribute payments based on the volume of production did not differentially influence income, net worth, and risk exposure across farm size. Furthermore, program options had less impact on farm growth than firm-level investment decisions.

"Less U.S. Government Intervention in Corn and Soybean Markets: An Analysis of Program Alternatives." Marshall A. Martin (Purdue University) and Mark A. Edelman (South Dakota State University)
Corn and soybean markets were analyzed with a multiperiod, stochastic simulation model. Elimination of current farm program provisions (deficiency payments, farmer-owned reserves, and CCC operations) increased price levels and variation but substantially reduced U.S. Treasury costs. Elimination of deficiency payments reduced U.S. Treasury costs by one-third but did not affect price behavior.

"Estimating the Effect of Government Programs on the Supply of Wheat in the United States." Bernard F. Neenan (Solar Energy Research Institute) and David Blandford (Cornell University)
Acreage functions for wheat, incorporating variables that reflect the value of voluntary acreage diversion programs to producers, are estimated for 1962–76. The elasticities of response to such programs are generally low in comparison to those for market price, indicating that the reduction of production through voluntary diversion is relatively expensive.

Fruits and Vegetables (Ed Jesse, NED ESS USDA, presiding)

"An Intraseasonal Model of the California Lettuce Industry." Sophia Wu Huang (IED ESS USDA)
An intraseasonal model of the California lettuce industry, consisting of four seasonal models with nine equations for each season, is developed and estimated. Some static and dynamic properties of the estimated model are analyzed.

"Flexible Postharvest Marketing Strategies for Pinto Beans." E. P. King and D. W. Lybecker (Colorado State University)
A model designed to identify optimal postharvest marketing strategies for pinto beans is presented. Both fixed and flexible strategies are evaluated. The flexible strategies use current market information monthly to determine whether or not storage should be continued. They clearly outperform fixed strategies for a risk-neutral decision maker.

"The Market for Winter Tomatoes: A Rational Expectations Interpretation." J. Scott Shonkwiler and Robert D. Emerson (University of Florida)
A model of the Florida tomato industry is formulated under the hypothesis that growers make production decisions as rational economic agents. This assumption implies that anticipated Mexican tomato imports as well as other economic variables are taken into account when the planting decision is made. Maximum likelihood estimation methods are used to solve the simultaneous equations model, and the implications of the model's reduced form are analyzed.

"Specifying a Weekly FOB Price Equation for Fresh Florida Limes." Robert L. Degner and J. Scott Shonkwiler (University of Florida)
Weekly data are analyzed to determine the relationship of Florida fresh lime prices to Florida lime shipments and Mexican fresh lime imports. A dynamic regression or transfer function model is specified for the lime price series. The identified and estimated transfer function models are found to correspond closely, and they highlight the pronounced effect of Mexican lime imports on Florida fresh lime prices.

Food Stamps and Other Food Programs. (Jean Kinsey, University of Minnesota, presiding)

"Food Aid Disincentives and Economic Development: Some Reconsiderations in Light of the Tunisian Experience." Mesfin Bezuneh and Brady J. Deaton (Virginia Polytechnic Institute and State University)

The disincentive effects of total food assistance on the Tunisian economy were analyzed using simultaneous equations. The analysis showed that no significant price disincentives were evident. The authors attributed these results to effective government pricing policy combined with a strong positive relationship between food aid and per capita income.

"The Food Stamp Program as a Categorical Grant: Impact on Participation and Costs." Kathryn A. Longen and Barbara A. Claffey (NED ESS USDA)
The expiration of the Food and Agriculture Act of 1977 in September 1981 suggests debate regarding the funding and operation of the food stamp program. In the past, proposals for a categorical or block grant approach to food assistance have been considered in Congress. This report provides an analysis of changes in benefits and participation under conversion to state administration of a federally funded food stamp program.

"Predicting the Direct Benefits of a Food Price Reporting or Preference Changing Program." W. H. Lesser and W. K. Bryant (Cornell University)
A method is developed for estimating returns to food price reporting and store selection preference-changing programs. The approach is demonstrated by an example. While the estimated return to preference changing is small, the direct savings for price reporting can be substantial. Further replications are required to verify these results.

"Evaluation of Food Consumption Programs: A New Approach." Donald A. West, Leon J. Hunter, and Charlotte B. Travieso (SEA USDA)
Microsimulation modeling allows the effects of food programs and changing socioeconomic and demographic characteristics on household food consumption to be estimated for future time periods. The paper presents the methodology, data base, and specifications needed to develop a framework for assessment of current and proposed food and nutrition programs.

Energy Demand Issues (George Norton, Virginia Polytechnic Institute and State University, presiding)

"Efficiency and Equity Aspects of the Solar Tax Credit and the Role of the Applied Economist." Robert Procter (Michigan State University)
Simulation results are used to argue that the federal solar tax credit violates both the equity and efficiency criterion stipulated by tax theory. We also argue that the efficiency criterion does not provide a useful decision criterion in policy analysis because such policies cannot be used to internalize externalities.

"Profit Volatility and Water-Energy Demand Elasticities in Citrus Production." Gary H. Wilkowske and Gary D. Lynne (University of Florida)
The demand for energy and irrigation water by the Florida citrus industry is shown to be relatively inelastic for energy price increases upward to 300%. As expected, product price increases have a more dramatic effect on profit than do energy price increases. A small product price increase can easily offset a much larger increase in energy prices.

"Economic and Energy Savings from Cogeneration: The Case of Surface-Heated Greenhouses." John B. Braden, Sheryl S. Lazarus, and Paul N. Walker (University of Illinois)
Heating greenhouses by applying waste-heated power plant cooling water to the outside surface could yield natural gas savings of up to 640 million therms and net present value (1980) savings of up to $2.8 billion for the continental United States.

"An Empirical Investigation of the Rural Cooperatives' Residential Demand for Electricity." Ruth J. Maddigan, Wen S. Chern, and Colleen A. Gallagher (Oak Ridge National Laboratory)
This study examines the Rural Electric Cooperatives' residential demand for electricity using a simultaneous-equation, partial-adjustment model. The structural equations are estimated using regionally pooled state-level, cooperative-specific data for the period 1969 to 1977. The results indicate substantial variability among regions in response to changing prices, income, and weather conditions.

Rural Development: LDCs (Eric Monke, University of Arizona, presiding)

"The Farm-Level Impact of Animal Draft Power: Survey Results from Upper Volta." Eric Crawford, David Wilcock, and Gregory Lassiter (Michigan State University)
Based on a 1978/79 survey in eastern Upper Volta, the paper examines the impact of animal traction on area cultivated, cropping pattern, yields, labor use, income, and cash flow. Potential returns to animal traction over time are summarized, and reasons for the gap between current and potential performance are analyzed.

"Tests For Relative Efficiency By Farm Size and Tenure Status of the Main Rice Crop in Bangladesh." Richard F. Nehring (IED ESS USDA)
A restricted profit function is used to estimate profit and factor demand functions from farm level cross-sectional data for the main rice crop in Bangladesh. Analysis indicates that large and small farms are equally efficient and that owners are more efficient in a price and technical efficiency sense.

"Small Farmer Loan Repayment Performance in Nepal." Krishna H. Maharjan (Agricultural Development Bank, Nepal), Chesada Loohawenchit (Thammasat University), and Richard L. Meyer (Ohio State University)

Study revealed that loan supervsion and collection were the most important variables explaining agricultural loan repayment behavior by small farmers in Nepal. Most studies categorize repayment factors into ability and willingness of farmers to repay. Willingness to collect and other institutional problems may be more important in many credit programs.

"Impact on Rural Inequality of Promoting Rural Nonfarm Activities: Evidence from Sierra Leone." Doyle C. Baker (Michigan State University)
This paper reviews evidence from Sierra Leone concerning the effect of promoting rural nonfarm enterprises on rural income disparities. The evidence indicates that policies promoting nonfarm enterprises may have a limited impact on the incomes of poorer rural households and could, in fact, lead to increased rural income inequality.

"A Comparative Method for the Collection of Labor Utilization Data for Secondary Crops: The Example of Cocoyam and Soybean Farming Systems Surveys in West Africa." Hendrik C. Knipscheer (International Institute of Tropical Agriculture, Ibadan, Nigeria)
Labor input data for secondary crops in developing countries are generally unknown because of the high data collection costs. The comparative method is an inexpensive way of labor input derivation where literature research and field surveys are combined. The labor data of selected food staples serve as benchmarks for the estimation of the labor utilization for secondary crops such as cocoyam and soybeans.

Farmland Purchase: Tax and Loan Considerations (Ivery D. Clifton, University of Georgia, presiding)

"The Decision to Buy or Sell Land Affected by Capital Gains and Income Tax Progressivity." John T. Scott, Jr. (University of Illinois)
A present value model estimates farmland price increases needed by investors in different tax brackets to equate land returns to an investment having higher current return but no change in nominal value. Higher bracket investors have greater advantage in land than low bracket investors. Also, inflation enhances this advantage.

"Graduated Payment Schedules For Farmland Purchases." Loren W. Tauer (Cornell University)
Expectation of increasing returns from farmland results in a higher market price than if returns were expected to remain constant. At this higher price, farmland can self-liquidate its own debt only if the payment schedule matches the increasing income stream. Graduated debt payment schedules can be used to accomplish this.

"Customer Profitability Analysis and Farm Loan Pricing by Agricultural Banks." Peter J. Barry and Rick R. Schramm (University of Illinois)
Profitability and pricing of farm loans by agricultural banks are analyzed. An empirical application to farm borrowers of an agricultural bank in Illinois indicates little relationship between customer profits and lending risk, liquidity risk, and other characteristics, thus showing strong potential for more effective loan pricing.

"Shared Appreciation Farm Mortgages: Consequences For Borrowers and Lenders." David Lins (ESS USDA/University of Illinois) and Clair Nixon (Texas A&M University)
Shared appreciation mortgages can help borrowers overcome the initial cash flow problems associated with the purchase of land while providing the lender a hedge against inflation. Procedures for evaluating shared appreciation mortgages versus traditional mortgages and renegotiable rate mortgages are presented.

Macroeconomic Issues in Agriculture (David L. Barkley, University of Arizona, presiding)

"Agricultural Prices in the 1970s and the Quantity Theory of Money." Richard C. Barnett (University of Minnesota), David A. Bessler and Robert L. Thompson (Purdue University)
The paper reviews early work on the quantity theory of money, notes extensions to analysis of relative prices, and tests the theory using Granger's causality definition with 1971–79 monthly time-series measures of U.S. and international money supply and U.S. agricultural prices. Results show money supplies lead prices by eight and sixteen months.

"Effect of Variable Interest Rate Loans on the Agricultural Sector." William McD. Herr, George A. Shumaker, Lyle Solverson, Thomas J. Dougherty, and Stuart Langrehr (Southern Illinois University)
Not only has income variability of important segments of the agricultural sector increased because of variable interest rate loans but this source of variability is significant. Among farm-sector expense items, we found total interest expense to be a major annual expense item and its coefficient of variation is as high or higher as other expense items including fertilizer, petroleum products, and feed.

"Agriculture's Financial Structure, Repayment Ability, and Capital Requirements During Inflation." William Burghardt (Michigan State University) and David L. Watt (IED ESS USDA/Michigan State University)
The agricultural sectors income statement was analyzed for the past thirty years and then projected through 1985 to evaluate agriculture's cash flow position. Then agriculture's debt repayment capac-

ity with and without nonfarm income was analyzed under three different assumed amortization rates.

"A Note on the Theoretical Specification of Wage Rates in a Cost-Push Model of Food Price Determination with Empirical Tests of Causal Orderings." Mike Belongia (NED ESS USDA/North Carolina State University)
Observed increases in nominal factor costs should not cause increased output prices unless nominal input costs increase more than factor productivity. However, cost-push models of food price behavior are often estimated using unadjusted nominal costs. Causality tests suggest adjusted wage growth and price increases are unrelated.

Risk (Mike Boehlje, Iowa State University, presiding)

"Estimation and Analysis of a Survival Function for a Simulated Wheat Farm." Larry J. Held (University of Wyoming) and Glenn A. Helmers (University of Nebraska)
A survival function developed for a simulated wheat farm reflects marginal survival odds decreasing with increased starting equity levels and more conservative borrowing limits for land expansion, but increasing with higher land appreciation rates. Iso-survival relationships show increasing requirements for more conservative borrowing at successively lower beginning equity levels.

"The Impact of Diversification on Farm Risk." Sheldon Zenger and Bryan Schurle (Kansas State University)
Using farm data, this study estimates the relationship between income and variability of income. The effect of diversification and other farm characteristics on income variability also is investigated. Gross farm income, acres per operator, taxable nonfarm income, and machinery investment per acre were significantly related to variability of net income.

"Farm Planning, Risk Aversion, and the Returns to On-Farm Storage Facilities." W. Donald Shurley (University of Kentucky) and George F. Patrick (Purdue University)
Risk is incorporated into an annual farm-planning model using the MOTAD framework. The availability of on-farm storage is an important and often forgotten resource constraint in the sensitivity of farm plans. Because farm plans are affected by risk aversion, so is the importance of storage facilities. Study results were highly sensitive to storage capacity and generally show that returns to storage are highest at low farmer risk aversion.

"A Risk Analysis of the Federal Crop Insurance Act of 1980." Randall A. Kramer (Virginia Polytechnic Institute and State University)
The Federal Crop Insurance Act of 1980 substantially expands the availability of crop insurance and provides for subsidies on premiums. Stochastic dominance is used to evaluate a variety of options available to farmers for using crop insurance to manage production risk.

Natural Resources: Methods (Linda Lee, Oklahoma State University, presiding)

"Common Property, Resource Rent, and Uncertainty: With an Application to the New England Groundfish Fleet." Peter H. Greenwood (University of New Hampshire)
The tendency for competitive users of a common property resource to exhaust the rent the resource is capable of producing has long been recognized. This paper argues that when competitive users must contend with uncertain returns, resource rent is not fully dissipated. When users are risk averse, their expected returns must be sufficiently greater than their certain opportunity costs to compensate for risk. It is argued that the additional returns are in effect a resource rent, since society could at no cost assume the fishermen's risk and appropriate the additional returns without affecting the equilibrium. Using historical data an attempt is made to assess the order of magnitude of risk in the New England otter trawl fishery.

"Bias in Recreation Benefit Estimates: Further Evidence." Kerry R. Livengood (University of Illinois)
Based on data from deer-hunting leases in Texas, a simultaneous model of the demand for deer-hunting trips, time spent at hunting sites per trip, and actual hunting lease cost is compared to demand derived by the travel cost method. The results suggest that bias associated with estimates of willingness-to-pay increases as travel cost decreases.

"Methodological and Empirical Considerations for Incorporating Fishing Power Functions in Bioeconomic Models." Timothy G. Taylor and Fred J. Prochaska (University of Florida)
The "correct" measurement of fishing effort is essential for the successful construction of fishery production and stock assessment models. A general method for measuring fishing effort in standardized terms on the basis of a fishing power function is presented. The results suggest this methodology to be superior to traditionally used effort measures.

"Methodological Ethics in the Evaluation of Nonmarket Goods Allocations." J. Walter Milon (University of Florida)
The ethical basis for economic evaluations of alternative nonmarket goods allocations is examined in terms of the treatment of property rights and intergenerational effects. The author argues that the theoretical and empirical conventions commonly adopted by resource economists are ethically biased and these ethical issues are worthy of more extensive debate.

"A Theoretical Model of Overgrazing in Traditional Livestock Economies of Africa: A Paradox of Perceived Values." G. M. Sullivan (Auburn University), K. W. Stokes and D. E. Farris (Texas A&M University)
Communal grazing is the major barrier to development of livestock economies in Africa. With a theoretical model, the paradox in a producer's perceived values for inputs and outputs in his livestock operation is examined to explain overgrazing. Analysis of government policies indicate improved livestock systems require appropriate institution building.

Livestock Sector Analysis (Terry Roe, University of Minnesota, presiding)

"The Hog Cycle Revisited." Thomas H. Spreen and J. Scott Shonkwiler (University of Florida)
The existence of a four-year cycle in hog production and prices has been well documented in the literature. Using recent data, however, this paper demonstrates that the cycle has become shorter with an average duration of approximately 3.2 years.

"The Economic Homogeneity of Grade Classifications Under the New and Old Feeder Cattle Grading Systems," James N. Trapp (Oklahoma State University)
A methodology was developed to determine the degree of economic homogeneity of a given grade class. A more homogenous grade grouping is argued to be desirable. The new feeder cattle grading system was found to provide a 12.5% less homogenous basic grade group class than the old system.

"A Disequilibrium Model of the U.S. Fed Beef Sector." Rod F. Ziemer and Fred C. White (University of Georgia)
In this paper current theory and estimation procedures are applied in an analysis of disequilibrium price behavior in the U.S. fed beef sector. Although tests of equilibrium versus disequilibrium hypotheses are not well developed, results indicated the possible presence of disequilibrium prices in the market for fed beef; at least the hypothesis of significant disequilibrium could not be rejected.

"Evaluating the Countercyclical Aspects of the U.S. Meat Import Act of 1979." James R. Simpson (University of Florida)
The potential effect of the new U.S. meat import law is analyzed under two radically different assumptions about buildup in U.S. cattle inventory. It is concluded that the bill is not truly countercyclical in nature because it only operates that way under special circumstances.

Food Demand (J. B. Wyckoff, Oregon State University, presiding)

"Life Cycle Effects on Household Away-From-Home and At-Home Food Expenditures." Stanley M. Fletcher (University of Georgia)
The influence of socioeconomic factors on food expenditures previously has been examined somewhat in isolation. The relative extent to which socioeconomic factors influence away-from-home and at-home food expenditure patterns across a household's life cycle was empirically investigated using the 1972–73 BLS Consumer Expenditure Diary Survey as the data base.

"Food-Away-From-Home Expenditures By Source of Household Income." Jean Kinsey (University of Minnesota)
Marginal propensities to consume (MPC) food away from home (FAFH) out of six sources of household income were estimated using Tobit and OLS. Marginal propensity to consumer FAFH was increased by income earned by children and part-time working wives and by transfer income in 1978. Full-time working wives' income decreased MPC.

"The Contribution of Basic Need Theory to Household Decision Making." Dorothy Z. Price and David W. Price (Washington State University)
Utility is viewed as consisting of five basic needs: physiological, security, love and belongingness, self esteem, and self actualization. Empirical applications are given in the areas of food consumption, food stamp participation, and job satisfaction. Potential value for integrating these psychological and economic constructs is discussed.

"Estimation of a Complete Disaggregate Food Demand System in the United States." Kuo S. Huang (NED ESS USDA)
Statistical procedures for computing the parameters of a highly disaggregated food demand system are developed. The procedures are then applied to the estimation of a U.S. food demand system consisting of forty-two commodities and one nonfood sector. Data are annual observations for 1953–77.

Economies of Farm Size (Sidney Bell, Auburn University, presiding)

"Impact of Selected Federal Tax Provision on the Growth of Two Cash-Grain Farms Differing in Size." Boris E. Bravo-Ureta (University of Connecticut) and Glenn A. Helmers (University of Nebraska)
A mixed-integer-polyperiod linear-programming model is used to evaluate the impact of selected federal tax provisions on the growth of two cash-grain farms. The results indicate that taxes differentially affect the growth of farms varying in size and thus can be important in determining the structure of cash-grain agriculture.

"Interfarm Variation of Cost of Production and Transportation, Yields, and Net Farm Income in the Canadian Prairies: An Econometric Analysis." Ihn H. Uhm and Andrew W. Gemmell (Research Branch, Canadian Transport Commission)
Size is the most important source of interfarm variation in the cost of grain production and transportation and in net income. Average transportation cost is a decreasing function of output, augmenting economies of size. Findings from the cost, yields, and net income models are consistent between single and multicrop samples.

"Resources and Economic Efficiency of Small and Large Farms: Selected Farms in Tennessee." Surendra P. Singh and Handy Williamson, Jr. (Tennessee State University)
The major objective of this study is to determine possible differences between production functions and differences in productivity levels as means to appraise resource allocative efficiency on small and large farms. Cobb-Douglas production functions were estimated using cross-section data collected from 193 randomly selected farm families in two counties of west Tennessee. The empirical results reveal that significant differences exist between the groups of farms. These differences are reflected by production functions and production elasticities of individual inputs.

"Estimates of before- and after-Tax Scale Economies for a Sample of Illinois Cash Grain Farms." Marvin T. Batte (Ohio State University) and Steven T. Sonka (University of Illinois)
The primary purpose of this study was to investigate the degree of economies of scale existing on a before- and an after-tax basis for a sample of commercial Illinois farms. Results of the analysis indicate substantial scale economies both before and after taxes for this sample of cash grain producers.

Marketing Issues (Ron Mittelhammer, Washington State University, presiding)

"Factors Influencing the Diversification of Food Manufacturers." James M. MacDonald (ESS USDA)
Product diversification, a common phenomenon, has been the subject of few empirical studies. I discuss issues in the definition and measurement of diversification, and then provide estimates of its extent among food manufacturers in 1975. Finally, I provide a statistical analysis of the differences across firms in the extent of diversification.

"An Evaluation of Alternative Indicators of Commodity Instability." Susan E. Offutt and David Blandford (Cornell University)
Data on ten U.S. field crops for the period 1950–77 are used to determine whether alternative single variable measures provide the same assessment of relative variability. The results demonstrate that the measurement and analysis of instability may be highly dependent on the choice of indicator.

"Theoretical and Empirical Considerations for Price Margins: An Application to the Striped Bass Market." Ivar E. Strand, Jr., and Robert E. Chambers (University of Maryland)
Using assumptions of competition and market equilibrium, a theoretical model of price margin behavior was constructed. Duality theorems with traditional comparative static analysis offered a specification of price margins in terms of shifters of supply and demand. The model was tested using wholesaler margins for East Coast striped bass. Factors positively related to marketing volume increased margins whereas those negatively related to volume reduced margins.

"An Empirical Analysis of the Cost of Long-Term Debt Financing for Cooperative and Proprietary Agricultural Marketing Firms." Peter Vitaliano (Virginia Polytechnic Institute and State University)
Regression analysis relating four measures of the cost of long-term debt financing to capital structure and other financial factors reveals this cost to be generally, but not in every circumstance, unrelated to a marketing cooperative's debt ratio and, in many instances, greater than this cost for a comparable proprietary firm.

"A Proposed Monitoring System for Detecting Violations of Capper-Volstead, Section 2." Edward V. Jesse (NED ESS USDA) and Aaron C. Johnson, Jr. (University of Wisconsin)
This paper presents a systematic procedure for monitoring agricultural marketing cooperatives for evidence of Capper-Volstead section 2 violations—unduly enhanced prices resulting from monopolization or restraint of trade. A screening process is proposed to identify cooperatives processing monopoly power as well as the ability to exercise monopoly power.

Regional Analysis (Craig L. Infanger, University of Kentucky, presiding)

"Sample Selection and the Problem of Unstable Base Relationships in Forecasting." William Gillis (University of Wisconsin)
Many regional analysts utilize econometric economic base models to estimate income multipliers in nonmetropolitan communities. Unstable base relationships caused by structural change within regional economies reduces the accuracy of forecasts derived from econometric results. This study applies a data pooling procedure to control the problem of unstable base relationships in forecasting.

"The Influence of Input Supply and Output Demand on Industrial Growth in the Rural Communities of Pennsylvania." Steven E. Hastings (University of

Delaware) and Frank M. Goode (Pennsylvania State University)
An important concept in location theory is the availability of intermediate inputs. This paper presents a conceptualization of intermediate input supply and suggests a variable to operationalize this concept. The variable is empirically implemented to test the relationship between the availability of intermediate inputs, market access, and industrial growth in rural communities.

"The Spanish Agricultural Growth Model: Implications for the Future." Philip F. Warnken and Charles C. Crissman (University of Missouri)
Spanish agricultural output has expanded at an average annual rate of 4% since 1960. In the absence of domestically generated technology, imported technology and imported agriculture inputs have been significant growth sources. Recent public policy emphasizing domestic technology generation promises potential for rapid future growth of Spain's agricultural output.

"A Model for Determining the Impact of Federal Outlays on County Well-Being." Marlys Knutson Nelson (EDD ESS USDA) and Luther G. Tweeten (Oklahoma State University)
A model is presented for evaluating federal spending to enhance well-being as proxied by personal income per capita, employment rate, private investment per capita, and population change. An application is illustrated. Based on results, it appears that federal programs are not highly effective in promoting the goals examined, and ways need to be explored to improve their performance.

Water Use and Quality (John Braden, University of Illinois, presiding)

"Special Assessment Tax for Water Quality Improvement." Nicolaas W. Bouwes, Sr. (NRED ESS USDA) and Peter Caulkins (University of Wisconsin)
Although it is recognized that there exists an unequal distribution of benefits associated with urban lake improvement projects, financing of such property typically relies on uniform property taxes which do not make this distinction. In this paper a more equitable tax, based upon a property value impact model, is proposed in which costs levied are commensurate with benefits received.

"Issues in Subsidization of Agricultural Nonpoint Pollution Control." William M. Park and Leonard Shabman (University of Tennessee)
Potential program cost savings in the form of reduced subsidy payments are estimated for a case study area from (*a*) targeting on the basis of land attributes and (*b*) increased education efforts. Discussion is also directed to the trade-off with increases in (*a*) information, contracting, and policing costs and (*b*) information and education costs.

"Efficiency and Equity Aspects of Policies to Control Sediment in the Altamaha River Basin in Georgia." Stan Spurlock and Ivery D. Clifton (University of Georgia)
Impacts on net farm income from policies to control sediment are analyzed with a linear programming model. Both efficiency and equity implications are presented under two policy alternatives. The level of subsidization for construction of terraces and alternative impacts when pollution abatement practices are implemented at the farm versus the basin level are analyzed.

"Residential Water Consumption with an Increasing Block Rate Structure." C. E. Young (NRED ESS USDA) and K. R. Kinsley and W. E. Sharpe (Pennsylvania State University)
Demand functions are estimated for the pre-rate change period using an error components regression procedure. Assuming no change in the rate structure, water use is predicted for the post-rate change period. Comparison of these use levels indicates that water use declined due to the imposition of the new rate.

Teaching, Extension, and Professional Activities (Larry Bohl, Purdue University, presiding)

"A Teaching Tool for Making Elasticity Relevant." David E. Kenyon and Karen P. Mundy (Virginia Polytechnic Institute and State University)
This paper explains the self-learning unit, "Forecasting Hog Prices Using Elasticities." It discusses the format of the self-learning unit, its forecasting ability, and its strengths and limitations for teaching a practical application of elasticities.

"Ethics, Research and the Agricultural Economist." David L. Debertin, E. Jane Luzar, and Eldon D. Smith (University of Kentucky)
The adherence to accepted canons of evaluation, or protocols, are distinguishing marks of scientific inquiry. Agricultural economics faces special problems which makes self-policing more difficult than in the non-social sciences. This paper examines reasons why research ethics should be of greater concern to agricultural economics. Case examples of situations involving ethics in research are examined.

"Comparing Loans: An Extension Program." Kim B. Anderson and Garnett L. Bradford (University of Kentucky)
The objective of this paper is to present a procedure for comparing alternative loans with different and/or unequal loan fees. The procedure is adaptable for use with calculators or microcomputers. An adjusted total loan cost and an approximate effective annual interest rate is produced for loan comparison.

"Determinants of Agricultural Economics Faculty Salaries." Josef M. Broder and Rod F. Ziemer (University of Georgia)
This paper reports findings of a study of agricultural economics faculty at land grant universities. Research and teaching activities are measured along with selected categories of faculty productivity. Within the context of a general salary model, monetary returns to research, teaching, and grantsmanship are examined along with other salary determinants.

"Migration Patterns of Students Receiving Ph.D. Degrees in Agricultural Economics in the United States." R. A. Schrimper (North Carolina State University)
The importance of different types of undergraduate institutions and interinstitutional migration patterns for individuals awarded Ph.D. degrees in agricultural economics is examined. A declining importance of land grant universities as a source of students, increased interinstitutional migration, and little change in time lags between degrees are indicated.

Rural Development: Public Services and Finance (Paul Gessaman, University of Nebraska, presiding)

"Distributional Aspects of a School Finance Formula among School Districts." Donald D. Osburn (University of Missouri)
This study was concerned with the school finance systems' recognition of differences in the local school district's ability to finance education. More specifically, this research was concerned with determining the effectiveness of the state aid formula (a new formula) in improving fiscal equity in Missouri school finance. The three measures of fiscal equity used in this study were expenditure uniformity, tax power equity, and wealth neutrality.

"Factors Influencing the Financial Viability of Nonprofit Primary Health Care Centers." Andrew C. Hunter and Sam M. Cordes (Pennsylvania State University)
Data were gathered in 1978 from seventy nonprofit primary health care centers (PHCCs) in Pennsylvania. These data were used for analyzing the financial viability of PHCCs. Financial viability is enhanced if the center (*a*) is not located near other physicians, (*b*) does not have a quality assurance program, and (*c*) is not overcommitted to administrative resources.

"Statewide Reassessment and Preferential Assessment of Agricultural Land: The Effects on Property Tax Incidence in Missouri." David E. Ervin (University of Missouri) and Robert M. Schoening (Milk Market Administrators Office, St. Louis, Mo.)
Recent appreciation of real estate values has unevenly eroded assessment levels from legal standards in many states. Inflation also has affected the determination of use values for agricultural lands. For Missouri counties, general reassessment is estimated to cause sizeable property tax shifts which ultimately would alter public service demands.

"The Direct and Indirect Effects of Population Growth on Homeowner Property Taxes." Shepard C. Buchanan and Bruce A. Weber (Oregon State University)
A model for estimating the direct and indirect effects of population growth on property taxes is fit to data for Oregon counties. Results suggest that increases in population did lead to increases in homeowner property taxes in the mid-1970s, primarily through the effect of population on assessed values.

Transportation Rate Structures (Phillip Baumel, Iowa State University, presiding)

"Ocean Freight Rate Variability as a Factor in International Agricultural Trade." James K. Binkley (Purdue University)
Due to inelastic shipping supply, ocean freight rates can fluctuate significantly over short periods. This variability can affect trade analysis. This paper presents evidence on rate variability and discusses possible implications for welfare gains from price stabilization and free trade, for comparative advantage, and for the effects of market power.

"Effectiveness of Competitive Forces to Limit Rail Rate Increases on Export Wheat Traffic in South Plains." Stephen Fuller and C. V. Shanmugham (Texas A&M University)
The paper relates results of research conducted to determine the effectiveness of competition to limit increases in rail rate levels under conditions of rail deregulation. The study focuses on the ability of intramodal and intermodal competition to constrain rail rate increases on South Plains export wheat movement.

"Estimation of Demand for Truck-Barge Transportation of Pacific Northwest Wheat." Charles Logsdon (Alaska Department of Revenue), Ken Casavant, Ron C. Mittelhammer, and LeRoy Rogers (Washington State University)
A conditional choice model was used to analyze truck-barge transportation demand. Truck-barge demand was found to be own-rate elastic but inelastic to rail rate changes. Transit time, equipment availability, and variance in waiting time were far less important compared to rates in determining modal choice.

"Factors Associated with Grain Rail Rates in Three U.S. Rate Territories." Michael J. Pesch and Donald W. Larson (Ohio State University)
Through regression analysis, the variability of grain

rail rates in three rail rate territories was found to be significantly explained by shipment size, traveling distance, and rail rate territory. Study results are discussed as they relate to the Staggers Rail Act of 1980 and alternative pricing policies.

"An Alternative Rate Structure for Assembling and Hauling Bulk Milk in Vermont." Fred Webster and Edward Karpoff (University of Vermont)
A revised rate structure for bulk milk hauling from Vermont farms is presented. Overcharging large-volume producers in favorable locations for milk hauling causes them to change haulers. Overhead costs per unit are thereby raised for remaining shippers. Revised rate structures could defer such a shift and help small farms.

Marketing Livestock and Grain (Lowell Catlett, New Mexico State University, presiding)

"Marketing Slaughter Hogs by Remote-Access Computerized Auction: Theory and Empirical Results." Dennis R. Henderson and E. Dean Baldwin (Ohio State University)
Electronic markets have been suggested as one means of reducing impacted pricing problems associated with thin, transparent trading of agricultural products. An experimental daily electronic auction was initiated for slaughter hogs in Ohio. Results in first four months show competitive price enhancement, improved price-quality relationships, and greater pricing efficiency.

"Electronic Meat Trading: Some Economic Considerations and Evaluation Guidelines." M. E. Sarhan (University of Illinois) and Kenneth E. Nelson (NED ESS USDA/University of Illinois)
The traditional exchange system for wholesale meat in the United States is under attack, partly because of alleged inefficiencies and equities in pricing. New marketing alternatives are under consideration, including electronic trading. This paper reviews the potentials of electronic trading for meat and suggests some economic considerations and evaluation guidelines.

"Distributional Aspects of the Farmer-Owned Grain Reserve under Alternative Risk Hypotheses." Andrew Morton, James Langley, and Earl O. Heady (Iowa State University)
A present-value certainty equivalence approach is used to assess the potential distributional aspects of participating in the farmer-owned reserve across farm size under risk. Even if the risk discount increases with farm size, other aspects favor participation of large producers enough to outweigh the risk factor.

"Managerial Inefficiencies in Rationalized Grain Marketing Systems." A. Clyde Vollmers and Stanley Thompson (Moorhead State University)
Economically inefficient managerial decisions may reduce the savings which rationalization of grain-marketing systems could potentially generate. Ineffective distribution, ownership, or transshipment patterns or modal selection decisions were estimated to total 3% of the marketing cost in one Michigan region. Thus, institutional design is critical in implementing system rationalization.

"The Impact of the Farmer-Owned Reserve on Market Structure: The Case of Wheat." William H. Meyers (Iowa State University) and Abner W. Womack and Maury E. Bredahl (University of Missouri)
The farmer-owned reserve is modeled as an endogenous variable in an econometric wheat model, and reduced-form impacts are obtained. The reserve equations, which are price elastic, add substantially to the elasticity of total market demand and significantly alter the impacts of exogenous shocks on price and other endogenous variables.

Farm Management Issues (Bill Boggess, University of Florida, presiding)

"Modeling Optimal Replacement Decisions for Farm Machinery: Some Theoretical and Empirical Problems." Garnett Bradford and Donald Reid (University of Kentucky)
Machine replacement research has concentrated on delineating and comparing present value (PV) and derived marginal analysis models. With such, one encounters problems in generating reliable estimates of new and used machine prices, repairs, and opportunity costs. Some empirical problems may be surmounted by altering the traditional PV framework, but theoretical considerations require more comprehensive models.

"The Economic Threshold as an Investment Problem." Mark Cochran and Lindon J. Robison (Michigan State University)
This paper develops the argument that the determination of the economic threshold and the underlying procedure defining optimal pesticide use is in reality a durable investment problem. It provides a conceptualization of the economic threshold that can guide research in the area to define more accurately the problem of optimal chemical usage.

"Multistage Optimization Using Separable Programming." Corbet J. Lamkin and W. Lanny Bateman (Mississippi State University)
This paper presents a case study of an integrated poultry firm with a plant location problem where two distinct processing functions are necessary and each process is subject to size economies. The problem was approached using separable programming. Results showed that separable programming is effective for problems involving multistage processing.

"Farmers' Goals: Uni- or Multi-Dimensional?" George F. Patrick and Brian F. Blake (Purdue University) and Suzanne H. Whitaker (Indiana Farm Bureau Cooperative)
Common goal measurement techniques implicitly assume farmers order goals on a unidimensional hierarchy. Multidimensional scaling (MDS) is proposed as an alternative conceptualization and scaling procedure. MDS scalings of farmers' goals were more consistent than with other methods. Risk-growth, monetary versus nonmonetary and wishfulness-practicality continuums were three dimensions identified.

Farmland Values and Conversion (Nelson Bills, NRED ESS USDA, presiding)

"Landowner Characteristics as Determinants of Developer Locational Decisions." Charles H. Barnard (NRED ESS USDA)
Discriminant and regression analysis show that the personal and financial characteristics of current landowners determine which urban fringe parcels developers select first. Normal conditions within the urban land market lead developers to choose those parcels that are owned by individuals with relatively low perceived present values for their parcels.

"A Market Equilibrium Approach to Determining Land Values." Lindon J. Robison and Thomas K. Espel (Michigan State University)
Models are developed for determining land prices in Walrasian market settings where land supplied and demanded is dependent on expected costs and expected benefits. The models, after being logically deduced, are tested empirically. The inflationary model without fixed land supply is validated empirically. The model including fixed land supply is rejected.

"A Pooled Time-Series Cross-Section Analysis of Land Prices." Jean-Paul Chavas and C. Richard Shumway (Texas A&M University)
Based on a theoretical formulation of land price formation as an economic rent to a fixed input, a single-equation econometric model is specified and estimated to explain land prices in five Iowa crop-reporting districts. It identifies the influence of farm prices, inflationary pressures, as well as land quality on the price of land.

"Analysis of Factors Affecting Rural Real Estate Values in Eastern Oklahoma." James R. Nelson and William E. Burton (Oklahoma State University)
The objective of the study reported was to examine factors that cause variations in rural real estate values in an eastern Oklahoma study area. Econometric models were developed to explain values of study area rural real estate in general and agricultural and nonagricultural real estate in particular.

Research, Development, and Technological Change (Carl E. Pray, University of Minnesota, presiding)

"An Analysis of Research Expenditures for Selected Agricultural Commodities." Nathan M. Garren (North Carolina State University) and Fred C. White (University of Georgia)
The empirical results of this study indicate the presence of externalities in agricultural research expenditures. An analytical framework is developed to account for these externalities in the allocation process. Allocations are examined both from the perspective of the state, acting in its own best interest, and from the nation's perspective.

"The Use of Genetics Principles in Research Evaluation—An Example with Soybeans." George W. Norton (Virginia Polytechnic Institute and State University) and W. B. Sundquist (University of Minnesota)
This paper explores the potential use of quantitative genetics principles in evaluating economic returns to plant-breeding research. Basic factors affecting genetic progress are described along with possibilities for quantifying them in relation to research expenditures. An example with soybeans illustrates how this information can be incorporated into *ex ante* research evaluation.

"An Economic Assessment of the Impacts of Public Funded Research on Corn, Soybeans, Sorghum, and Wheat." Daniel M. Otto and Joseph Havlicek, Jr. (Virginia Polytechnic Institute and State University)
The framework of a supply response model is used to evaluate individually the impacts of research expenditures on yields of corn, wheat, soybeans, and sorghum. Based on pooled data from a cross-section of states for the 1973–79 crop years, the Parks procedure was used to estimate internal rates of return of 71%–97% for own-state investment and 5%–47% for spillovers of outside research investment. Yield-response price elasticities indicate wheat yields were most responsive and sorghum yields were least responsive.

"Crop Improvement Strategy: An Analysis of the Potential Benefits of New Cassava Production Technology in Colombia." Douglas Pachico (International Center for Tropical Agriculture, Cali, Colombia)
The potential benefits of cassava varieties suitable for the feed market are estimated. A linear programming feed-mix model simulates the cost reduction in feed resulting from cheaper cassava. Then, elasticities of demand and supply of poultry are estimated to calculate economic surplus from the new technology.

"The Impacts of Government Production-Oriented Research and Extension on U.S. Agriculture: A Simulation of Future Alternatives." Roland K. Roberts (University of Hawaii) and Raymond Joe Schatzer and Earl O. Heady (Iowa State University)

This paper explores the effects on U.S. agriculture of alternative future assumptions relating to the growth in real government expenditures on production-oriented research and extension. Results suggest that increases in the rate of growth in research and extension above-average historical levels could cause agricultural prices and incomes to decline substantially. However, crop exports would only have to increase above projected trend levels by approximately 6.5% to maintain crop prices.

Pest Management (Katherine Reichelderfer, NRED ESS USDA, presiding)

"A Simple Model to Determine the Economic Threshold of Beef Cattle Pests with Limited Entomological Information." Assam M. Azzeddine and Maurice Baker (University of Nebraska)
Existing models for defining the "economic threshold" for pest control have been developed largely for crop damage assessment and require data not presently available. These models are modified to construct a workable approach to a livestock pest problem based on limited entomological information.

"Estimating Benefits from Controlling Nuisance Pests: An Application of the Iterative Bidding Technique." Darrell Hueth (Oregon State University), Steve Voorhees (University of Wisconsin), and Richard Casagrande (University of Rhode Island)
This paper presents some results on the application of the iterative bidding technique to estimating benefits from reducing gypsy moth infestations in the Northeast. Benefits are calculated under the assumptions that (*a*) a chemical spray is the only control technique variable, and (*b*) that there exists some completely environmentally safe technique for controlling the pests. The difference between estimates and benefits obtained under these two situations is interpreted as the estimate of environmental cost resulting from using chemical sprays. Also, this research is generally encouraging insofar as the usefulness of the iterative bidding technique itself is concerned in that the empirical results are largely consistent with a priori theoretical hypotheses.

"The Contribution of Herbicides and Other Technologies to Soybean Production in the Corn Belt Region, 1965 to 1979." David Schroder, J. Charles Headley, and Robert M. Finley (University of Missouri)
This report attempts to identify the contributions of technology and weather to soybean yield variation for the period 1965 to 1979 in the Corn Belt. Technology variables included genetic improvement, herbicides, and row-width. A pooled, cross-sectional, time-series data base was used to estimate regression parameters for herbicides and other variables. A marginal private benefit/cost return of $2.3 per dollar of herbicide cost was estimated for additional land treated with herbicides.

"Use and Benefits of Kalman Filtering for Insect Pest Management." Luis R. Zavaleta and Bruce L. Dixon (University of Illinois)
Efficiency of pest scouting is shown to be increased substantially by utilizing a model of pest evolution between sampling periods in addition to sampled data. The Kalman filter is the estimator used, applied to the bean leaf beetle in Illinois.

Input Demand (Lee F. Schrader, Purdue University, presiding)

"A Canonical Correlation Analysis Relating Farmer Characteristics to Service Demand in the Purchase of Farm Inputs." L. A. Johnson and W. A. Thomas (University of Georgia)
The purpose of this paper was to identify farmer characteristics which affect demand for farm services. Data included surveyed responses from 277 farmers located in selected southeastern areas. The canonical correlation procedure was used to test the assumption that the characteristics were not independent of each other.

"Optimal Asset Replacement under Conditions of Technological Change: The Case for Improved Fuel Efficiency." F. Allen Morris (A. Duda & Sons)
This study analyzed the effects of technological change, measured as improved fuel efficiency, on the optimal timing of replacement for pickup trucks used on corporate farms. It was found that annual mileage, fuel price, and level of fuel efficiency of potential replacements all affect optimal replacement times.

"Demand Elasticities and Cross Elasticities for Diesel Fuel—Crop Producers." Francis P. McCamley and James B. Kliebenstein (University of Missouri)
A quadratic programming model was formulated to examine diesel fuel demand by a representative risk-averse crop producer. Demand was examined by varying energy prices, crop prices, and degree of risk aversion. Wheat and soybean prices and producer's attitude toward risk had greater impacts on fuel use than energy prices.

"Demand for Farm Tractor Horsepower in the United States." Dennis M. Conley and Douglas A. Lambert (University of Illinois)
Since the mid-1960s there has been a shift in the composition of tractor horsepower purchases. Models of annual demand were estimated for the 1950–78 time period. Significant explanatory variables included tractor prices, prices received, stock of horsepower on farms, interest rates, farm employment, self-propelled combines, and acres planted.

Econometrics (Peter Greenwood, University of New Hampshire, presiding)

"Detection and Treatment of Multicollinearity in Simultaneous Systems of Equations." Ralph R. Semprevio (Chase Econometrics) and Oral Capps, Jr. (Virginia Polytechnic Institute and State University)
Methods to detect the extent of multicollinearity in simultaneous systems are put forward. To treat multicollinearity problems, the integration of the Ridge Regression technique with the 2SLS technique is proposed. The RR2SLS procedure is then empirically evaluated vis-à-vis the 2SLS procedure.

"Prior Linear Constraints on Parameters: Will Their Use Mitigate Specification Error?" Ron C. Mittelhammer (Washington State University)
The paper defines the theoretical problem conditions under which restricted least squares (RLS) is superior to OLS in predictive risk when misspecification exists. Unfortunately for applications, the *F*-test of RLS superiority is biased and has undesirable power characteristics, and the use of correct prior constraints can accentuate predictive risk.

"Criteria for Model Specification of Demand Systems." Oral Capps, Jr., and Joseph Havlicek, Jr. (Virginia Polytechnic Institute and State University)
Four general principles are formulated as criteria for model specification of demand systems. The concepts shed light on systems credibility, validation, strengths, and weaknesses. The principles are used to judge the empirical performance of the S_1-branch system.

"Error Specification in Transformed Models." David Smallwood and James Blaylock (FE NED ESS USDA)
Autocorrelated residuals and a heteroskedastic error variance are both jointly and separately incorporated into a Box-Cox transformed model. A quarterly demand equation for pork is used for purposes of illustration. Results indicate that both functional form and error term specification play a crucial role in hypothesis testing and estimation of elasticities.

Soil Erosion (David J. Walker, University of Idaho, presiding)

"A Regional-National Model for Agricultural Policy Analysis with an Application to the State of Iowa." Wen-yuan Huang (NRED ESS USDA) and James A. Langley and Earl O. Heady (Iowa State University)
A Regional-National Model has been constructed and can be used as a tool to estimate the regional effects of a national policy and to evaluate the national implications of regional policy alternatives. A Regional-National Model of soil erosion in Iowa is presented as an illustration of this modeling technique.

"Risk Perceptions and the Utilization of Conservation Tillage Practices." James S. Shortle and John A. Miranowski (Iowa State University)
The relative risk of alternative tillage practices perceived by farmers and the determinants of these perceptions are considered. Survey data are used to estimate relations between perceptions of relative risk and farm operators' human capital and farm operation variables. The implications for effective soil erosion control policy are discussed.

"Impact of Erosion Control Policies on Wildlife Habitat on Private Lands." John A. Miranowski and Ruth Larson Bender (Iowa State University)
This study indicates that erosion control policies designed to maintain soil productivity and improve water quality tend to enhance wildlife habitat quality with varying degrees of effectiveness. Habitat indexing and valuation procedures are considered in conjunction with a programming model of the Iowa River Basin to illustrate these effects.

"The Influence of Technological Progress on the Long-Run Social Returns to Soil Conservation." Daniel Taylor, Douglas Young, and David Holland (Washington State University)
Appropriate multiplicative interaction between technological progress and yield-topsoil functions was incorporated in a systems simulation model projecting Palouse topsoil levels, crop yields, and net incomes. Results revealed high payoff to soil conservation on shallow soils and for longer planning horizons. Yield projections were more optimistic than farmers' subjective projections.

International Trade (Robert Chambers, University of Maryland, presiding)

"U.S. Trade in Consumer Products." Philip Garcia, Mary Anne Ross, and Daniel I. Padberg (University of Illinois)
The United States has experienced a large trade deficit in consumer products. It is hypothesized that the institutional frameworks in which consumer products are marketed have adversely affected our trade in consumer products. Trade policy alternatives should recognize these institutional differences and their implications for our trade situation.

"Effects of European Export Subsidies on Changing Levels of U.S. Poultry Meat Exports in World Markets." Glenn C. W. Ames and John W. McClelland (University of Georgia)
The European Community (EC) is the world's largest exporter of poultry meat and eggs. EC export subsidies have lowered the effective price of poultry exports and expanded the demand for its product. As a result there has been a substantial substitution of EC poultry for U.S. products in world markets.

"Developing a Prototype Model for the World Grains, Oilseeds, and Livestock Model." Karen Liu (IED ESS USDA)
In order to develop an improved specification for the grains, oilseeds, and livestock world trade model and to cope with the problems identified in the present GOL model, an aggregate three-commodity, two-region prototype model is developed. The major emphasis on the model structure is using nonlinear functional forms and incorporating trade restrictions in the model.

"The Effect of Bilateral Trade Agreements on World Trade and Price Stability." Alan J. Webb (IED ESS USDA)
A theoretical model is developed which shows that the aggregate effect of an increase in bilateral trade agreements is an increase in the variability of world prices and trade. For a single country, the model shows that it is to each country's advantage to keep its bilateral commitments from exceeding its expected trade.

"The Impact of Structural Change on Potential Instability in the World Wheat Market." Nancy E. Schwartz and David Blandford (Cornell University)
The relative decline in wheat consumption in the developed countries is reducing the potential stabilizing effect on the world market of freer trade in these countries. Furthermore, the growing role of centrally planned countries as importers is increasing the potential instability in world wheat import demand.

Labor (James Holt, Consulting Agricultural Economist, Washington, D.C., presiding)

"Econometric Simulation Approach to Evaluating the Impact of a Technological Change." Jon A. Brandt (Purdue University) and Ben C. French (University of California, Davis)
An econometric model of the processing tomato industry simulates price, production, and employment levels with and without adoption of the mechanical tomato harvester. Acreage increased by 30,000 to 85,000 acres, and grower prices declined by $6.84/ton to $19.51/ton with harvester adoption. Displaced harvest labor was largely offset by increases in assembly and cannery employment.

"Farm Household Production: Demand for Wife's Labor, Capital Services, and Capital-Labor Ratio." Mark Lange (St. Cloud State University) and Wallace E. Huffman (Iowa State University)
Model of farm household resource allocation and econometric estimates of equations explaining absolute and relative factor intensities of household production are developed. Empirical results indicate the gross substitute nature of wife's household labor and capital services. Importance of separation of home labor and leisure are also demonstrated.

"An Econometric Analysis of the Market for Casual and Other Hired Farm Labor." Lewell Gunter and Ann Vandeman (University of Georgia)
This is a time-series supply and demand analysis with hired farm labor disaggregated into casual and noncasual categories. Man-days worked is used as an endogenous variable rather than the number of workers. The model specification and data source differ from previous studies and results are compared to previous studies.

"Off-Farm Labor Supply in a Developing Economy." Dwight A. Smith and Richard L. Meyer (Ohio State University)
This paper reports on a study testing the new household economics for explaining off-farm labor supply of a sample of Philippine farm households. Labor supply for husbands was very elastic with respect to off-farm wage rates. Farm size and number of children were also important explanatory variables.

Synthetic Fuels (Loyd Fischer, University of Nebraska, presiding)

"The Feedback Effects of Higher Oil Prices on Production of Biomass Alcohols and Synfuels." John D. Hoff and Wallace E. Tyner (Purdue University)
A biomass alcohol sector was added to an energy macromodel to examine the effect of oil price feedbacks on the production costs and development of biomass alcohols and synfuels derived from oil shale and coal. Coal liquids costs were most sensitive to oil price increases, while biomass alcohol costs were least sensitive.

"Market Implications of Soybean Oil Use as a Diesel Fuel Substitute." Richard A. Levins (Mississippi State University) and William H. Meyers (Iowa State University)
Soybean oil is being considered as a diesel fuel substitute by both the United States and Brazil. Impacts of a fuel substitution program by each country on the U.S. soybean industry are evaluated. Export values and oil prices increase, but there are negative impacts on the meal sector.

"A Comparison of the Economic and Technical Potential of Small-Scale Alcohol and Sunflower Oil Production." Robert C. Reining and Wallace E. Tyner (Purdue University)
The technical and economic feasibilities of three scales of on-farm grain alcohol production are compared with three similar scales of sunflower oil production. Sensitivity analysis is conducted for different operating conditions, feedstock costs, and byproduct values. Sunflower oil is generally competitive with alcohol if there are no government subsidies.

"Crops for Food or Fuel: An Estimate of the Trade-off." Jerry A. Sharples (IED ESS USDA)
The production of an additional two billion gallons of ethanol from corn in the United States would increase the world price of grain about 6%. This result was obtained using a simple two-region world model of the grain-soybean market. Welfare implications are also obtained.

Commodity Futures (Anne Peck, Stanford University, presiding)

"Commodity Futures Price Theory for Semistorable Products." Steve Blank (California Polytechnic State University)
The objective of this paper is to specify and test a basic futures price theory for semistorable products. Both live and feeder cattle are tested as examples because it is expected that they will have some characteristics of both perfectly storable and perfectly nonstorable products. Feeder cattle proves to be more storable.

"An Econometric Model of Hedging, Speculation, and Volume in Commodity Futures." Ronald W. Ward and Robert M. Behr (University of Florida)
Hedging and speculative use of futures trading evolves out of the expected benefits from holding futures contracts. These trading positions are interrelated and are influenced by factors such as the levels of price risk, the degree of competition, the extent of government regulations, and alternative investment opportunities. An econometric model using pooled cross-sectional and time-series data on a three-equation system is used to explain hedging, speculation, and volume activity.

"Hedging Pork Products Using Live Hog Futures: A Feasibility Analysis." Marvin L. Hayenga and Dennis DiPietre (Iowa State University)
The feasibility of hedging ten wholesale pork products using the live-hog futures market was analyzed, and appropriate hedging relationships were estimated using 1970–79 data. Depending upon a firm's risk aversion, the live-hog futures market could be a useful risk management tool for meat processors and merchandisers dealing with pork products.

"Using Mechanical Trading Systems to Evaluate the Weak Form Efficiency of Futures Markets." Paul E. Peterson and Raymond M. Leuthold (University of Illinois)
A methodology is developed for using mechanical trading systems to evaluate the weak form efficiency of futures markets, including a method to statistically analyze trading results generated by these systems. These techniques are then used to test the weak form efficiency of the hog futures market from 1973 to 1977.

Editor's Note:
These Selected Papers have been filed with University Microfilms. That firm will provide microfilm, microfiche, or hard copy for a small fee. Write Xerox University Microfilms, 300 North Zeeb Road, Ann Arbor, Michigan 48106.

Award-Winning Theses

Barnett, Richard Clay. "The Relationship between Domestic and International Liquidity and Nominal Agricultural Prices: A Time-Series Analysis." M.S. thesis, Purdue University, 1980.

No empirical evidence has been brought forth to test empirically whether recent increases in international liquidity have had any sizeable impact on the prices of many agricultural commodities traded internationally. Further, few studies have analyzed the effect these monetary variables have had on the ratio of agricultural prices to prices in the rest of the economy. This thesis represents an attempt to develop a theoretical model which explains the relationships between nominal and relative agricultural prices and money in a macroeconomic setting, as well as to test empirically these relationships using a variety of time-series methods.

The empirical evidence suggested that domestic and international monetary expansion had a significant effect on domestic agricultural and food prices in the United States and in the world in general during the 1970s. Monetary expansion also appears to have had an influence on the observed changes in the ratio of U.S. agricultural prices to nonagricultural prices during this period. The empirical evidence also suggested that money is causal to agricultural prices, with little or no feedback.

Rucker, Randal Ray. "The Dynamics of Montana Beef Cattle Inventories." M.S. thesis, Montana State University, 1980.

Models for estimating beef cattle herd sizes in Montana are estimated using a nonlinear least squares algorithm. The use of this algorithm allows the estimation of "nonstochastic difference equations" in which the stochastic component is purged from the lagged values of the dependent variable. Models are developed to explain the levels of total herd sizes as well as the levels of breeding herds. Explanatory variables in these models include the levels of hay production, beef to corn price ratio, and calf (or feeder steer) prices in preceding periods. Interpretations of the estimated distributed-lag patterns and of the nonstochastic forms of the difference equations are offered. The models estimated in this thesis appear to offer an improvement over previous attempts to explain and model beef cattle herd sizes.

Semprevio, Ralph Robert. "Estimation of Economic Structural Parameters and Multipliers under Conditions of Multicollinearity in Simultaneous Systems." M.S. thesis, Virginia Polytechnic Institute and State University, 1980.

The specific objectives of this research were fourfold: (*a*) to detect the extent of multicollinearity in simultaneous systems of equations; (*b*) to develop the Ridge Regression (RR) biased-estimation technique within the context of the two-stage least squares (2SLS) framework; (*c*) to compare the 2SLS procedure using RR integrated into the first- and/or second-stage estimations of the standard 2SLS procedure; and (*d*) to investigate the empirical applicability of using RR in the estimation of simultaneous systems of equations.

Three estimation procedures were compared: (*a*) the standard 2SLS procedure, (*b*) a technique involving RR in the first-stage estimation and ordinary least squares in the second stage (RO2SLS), and (*c*) a technique using RR in both the first- and second-stage estimations (RR2SLS).

The empirical applicability of using RR in the estimation of simultaneous systems was assessed through the estimation of a pork sector supply-demand model and a wheat sector-demand model. The estimation techniques were compared on the basis of total mean squared error (TMSE) and multiplier "sensibility."

The RR2SLS procedure is recommended as an extension of the 2SLS technique. This technique should be used when interpretation problems arise with respect to the 2SLS estimation results and prescribed multicollinearity indicators suggest a severe multicollinearity problem. The RO2SLS procedure is not recommended because, in this study, the estimation results were unimproved in comparison to those obtained with the 2SLS procedure.

Easter, Christopher Douglas. "Supply Response with Stochastic Technology and Prices in Australia's Rural Export Industries." Ph.D. thesis, University of California, Davis, 1980.

The primary purpose of this research was to explore the theoretical and empirical issues involved in the specification of a stochastic model of supply response in the Australian grazing industry. The second aim of this investigation was to estimate the responsiveness of the main rural export products to changes in output prices.

Unusual among developed countries, Australia still relies extensively on the rural sector for the generation of export revenue in the economy. A salient feature of those markets is their volatility, leading to price variability for Australian producers. Fluctuating seasonal conditions in the country impart to producers a second element of uncertainty—production risk. The stochastic programming model developed overcomes problems of

dimensionality or approximation, previously encountered in programming methodology, and successfully incorporates technological and price risk.

The model was

$$\text{maximise } \mathbf{E(p)'x} - \frac{\phi}{2}\mathbf{x}'\Sigma_p\mathbf{x},$$

such that

$$\mathbf{E(A)x} + [(\mathbf{x} \otimes \mathbf{I})'\Sigma_A(\mathbf{x} \otimes \mathbf{I})]^{\frac{1}{2}}\theta^{-1}(\alpha) \leq \mathbf{b},\ x \geq 0,$$

for $\mathbf{E(p)}$, a price expectations vector; $\mathbf{x}$, an activity level vector; ϕ, the Arrow-Pratt risk aversion coefficient; Σ_p, a price variance-covariance matrix; E(A), an input-output expectations matrix; Σ_A, a technology variance-covariance matrix; $\otimes$, the Kronecker product; I, an identity matrix conformable with $\mathbf{x}$; $\theta^{-1}(\alpha)$, a vector reflecting probabilities with which constraints are satisfied; and $\mathbf{b}$, a resources vector. Risky prices are represented in the maximand and stochastic technology introduced via chance constraints. Since deterministic equivalents of the chance constraints are nonlinear, it was not possible to solve the above model using conventional algorithms. Rather than approximating the solution using linearization procedures, iterative application of the asymmetric quadratic programming (AQP) algorithm was used.

The approach used met with considerable success. Examination of the convergency properties showed that the feasible solution set for the AQP problem contained the feasible solution set for the iterative model. Further, it was demonstrated that the existence of an optimal solution in the conventional AQP model was sufficient for there to exist an optimal solution for the iterative model with stochastic technology. Empirically, the success of the approach was reflected in the number of cycles of the model (5–8) required to achieve convergence.

In addition, performance functions were derived, graphical representation of price responses depicted, and own-price and cross-price elasticities of supply estimated for beef, wool, sheepmeats, and wheat. The vast information set generated by the model provides a useful framework within which the supply and revenue impacts of changes in domestic policy on the grazing industry can be assessed. Similarly, the model is useful in estimating output changes effected by policies implemented in importing nations.

Johnson, Frederick Ian. "An Analysis of Brazil's Sugar Program, 1953–1975." Ph.D. thesis, University of Minnesota, 1980.

Since 1931 Brazil has protected and regulated its domestic sugar industry. This study examines, in the context of a supply and demand analysis, how Brazil's sugar program has affected its domestic and foreign sugar market. The analysis covers the two key instruments of the sugar policy (the setting of prices and the restricting of sales); it considers separately the two main regions (the North-Northeast and the Center-South); and it encompasses primarily the period 1953–75.

The first step in the analysis is the construction of a model of production in which crop yields are stochastic. Several quota systems are considered, and in each case the producer response to the quota is inferred. It is shown that, in this stochastic framework, the quota can be treated as reduction in the effective price received by the farmer. The fraction by which the actual price is effectively reduced hinges upon the size of the quota and on the moments of the distribution of crop yields. Acknowledging the stochastic nature of the crop allows the estimation of the effective price and, in turn, the estimation of the free-market supply relation.

Supply and demand are then estimated. Employing these estimates, the impacts of the quotas are examined by simulating no-quota production, and the effect of price setting is examined by simulating production and consumption at world prices.

Stoll, John R. "The Valuation of Hunting-Related Amenities: A Conceptual and Empirical Approach." Ph.D. thesis, University of Kentucky, 1980.

A conceptual framework for the valuation of wildlife resource-related amenities is presented in this dissertation. The "new theory of demand," developed by Lancaster and other researchers in household production theory, are utilized in the development of this conceptual framework. Activity and existence values for resources are conceptualized. The end product is a framework which can be used in the collection of data, data analysis, and provision of information for wildlife resource management purposes. Hicksian measures of welfare change are also redefined within this framework, and a unique notation is introduced for their representation. These measures can be used to determine the impact upon households of changes in wildlife populations. Total value and compensated demand curves for the wildlife resource are defined.

An empirical application is presented and used to estimate values for elk hunting-related amenities in Wyoming. This application uses the iterative bidding form of contingent valuation techniques. In this case study, mean household willingness to pay (WTP) annually for the right to hunt elk is estimated to range from \$44.09 to \$126.04, depending upon the elk/encounter package. Previous methods of estimating models using iterative bidding results are substantially improved in this study. Theoretically relevant variables are identified using the developed conceptual framework: (*a*) variables defining the specific consumption package, (*b*) variables isolating differences in household consumption technology, and (*c*) variables indicative of differing tastes and preferences. The final estimated

model adopted for further use utilized income-categorized data and included variables which allow for variation in household consumption technology. This model resulted in an estimate of an income elasticity of bid equal to .369 which, in this model specification, is also equal to the price flexibility of income for elk encounters. A new method for handling "poor" respondents to iterative bidding formats is also discussed.

The estimated model is used to determine a total value curve for the right to hunt elk. From this total value curve, a compensated demand curve for elk encounters is derived. The estimated annual marginal value of an additional elk encounter is $3.65 when the household typically encounters five elk. The estimated annual total value of the right to hunt elk is $95.98 when six elk are typically encountered.

AAEA Business

Committee Reports

Report of the President

The state of the Association is sound. The past year is best characterized as one of consolidation and growth: growth because as of this date it appears that 1981 membership will be up from last year by 300 or more; consolidation because new editor James Houck, associate editors Frank Smith and Ben Senauer, secretary-treasurer Sydney James and business office director Wes Ebert are functioning well. Inflation coupled with transfers of editorship and the business office to new locations sharply raised costs, but, thanks in no small part to the Finance Committee headed by John Hopkin and to prudent investment of our financial assets by John Brake and his Investment Portfolio Subcommittee, the expected budget surplus for 1981 is $17,400 and no membership dues increase is necessary.

Sydney James and Wes Ebert have made substantial progress in computerizing membership files. This activity already provides payoffs in terms of readily accessible information for Association officers, the Membership Committee, and the *Handbook-Directory*. In these and a host of other potential uses, the payoffs come at a cost, not the least of which is the burden on membership of providing biographic data.

The Executive Board at its December 1980 meeting made the decision to use the Employment Registry form to collect biographic data because it was comprehensive in scope, available, and because the Department of Labor covered costs of forms and mailing. From the standpoint of the Illinois Job Service, the solicitation was a huge success, with approximately 2,200 persons entering the Employment Registry. From the standpoint of the *Handbook-Directory*, the solicitation fell short of success with approximately 1,800 members failing to complete the form. The Executive Board concluded that it is unwise to go to press under such circumstances, and Sydney James will send out an abbreviated form with membership dues notices for those who have not completed the required form. For those who have provided biographic data, a printout of information on file will be sent with the dues notices to provide opportunity for correction and update.

To minimize respondent burden in future years, basic biographic data will be printed on dues notices for updating and correction, and only new members will need to complete a comprehensive form. (I digress to note that the Executive Board requested that in the future, questionnaires mailed to AAEA members using membership lists provided by the secretary-treasurer be screened by the secretary-treasurer to avoid undue length or excessive coverage of membership.)

With the convenience offered by the electronic computer, a new *Handbook-Directory* can be printed as comprehensively as needed, with an abbreviated, low-cost directory of names, addresses, and telephone numbers printed annually if desired.

The Handbook-Directory Committee chaired by David Boyne has been a big help in deciding what data to include in the computerized membership file. That committee has been able to draw on the prior thinking and recommendations of the Operational Data Base Committee, of which Ken Farrell is chairman. The work of these committees is largely completed.

In reading reports of former presidents, I note the same thing impressed them that most impressed me—the complexity and breadth of participation of membership in the Association. I have appointed approximately 300 committee members and worked hard to involve a representative cross-section of the membership. This annual meeting, alone, features nearly 70 sessions, and each of these sessions averages several participants.

I have never worked with people more willing to give of themselves. Reasons for this willingness include recognition and another citation in ones vita, but much of the generous participation is selfless dedication to a strong sense of community in the Association. AAEA is a family. Maintaining that treasured sense of family is difficult and some members and groups get the feeling they are distant cousins—once or twice removed! Making these latter individuals and groups feel they are full participants whose needs are being met challenges the Executive Board. The Board is exploring alternative program formats and publication outlets for better ways to serve the diverse needs of the profession without sacrificing the needs of others. I report some of those activities below and offer additional comments in the September *AAEA Newsletter*.

I appointed ad hoc committees to examine the professional role and status of women, chaired by Ardelle Lundeen, and the role and status of blacks, chaired by Sidney Evans. The committee on women performed a comprehensive study reported in an invited paper session to be published in the December *Journal*. The committee on blacks is making progress and will provide a comprehensive report later. The Executive Board elevated the women's committee, based on their request for needed continuity, from ad hoc to special committee status.

The Professional Activities Committee (PAC) stimulates the Executive Board to devise ways better to serve the membership. PAC, under the leadership of Sam Cordes, brought before the Board several suggestions for improving the annual meet-

ing planning and program format. An ethical conduct policy proposed by PAC, for the Association committee members, directors, and officers was adopted by the Executive Board for inclusion in the bylaws.

In what can be a significant new development for the Association, the Executive Board asked Ed Schuh to appoint a committee to examine the opportunity for a new publication of the Association that will emphasize less esoteric research methodology and emphasize more effective communication of applied economics of interest to practitioners in teaching, extension, industry, administration, and research. Such a publication can be of great value in meeting the diverse interests of our members.

Following recommendations of the Professional Activities Committee, the Executive Board voted to cosponsor with Farm Foundation a conference, "Perspectives on Agricultural and Food Policy Research"; with USDA a conference on "The Economics of Food and Agricultural Trade"; and with the American Society of Agricultural Engineers two conferences, "Second International Livestock Environment Symposium" and "International Conference on Plant and Vegetable Oils."

The Membership Committee led by Gene Mathia used the campus recruiter approach this year to reach prospective and delinquent members. The system seems to have worked, based on the increase in membership. In future years, computerized membership files can give continuous feedback showing the success of each recruiter.

Thanks to special effort by the Resident Instruction Committee chaired by Duane Harris, the long-awaited and popular brochure "Careers in Agricultural Economics" is being printed in revised form this year. Contact Duane for copies, which can be purchased at cost. In part because of a new Student-Section administrative structure, student activities including presentation and judging of papers seems to be functioning smoothly this year. Students are the future of the profession, and the Board wishes to do what it can to encourage growth and activity of the Student Section.

Under leadership of Gary Seevers, the Industry Affairs Committee had a banner recruiting year, increasing membership 40%! They also sponsored the Industry Banquet and a symposium at the annual meeting.

The American Agricultural Economics Documentation Center in the USDA is gaining increasing recognition and use and is inputting 550—600 refenrences per month. The Board's confidence in the Center is apparent in $21,000 of Association funds allocated to provide a portion of the Center's cost, borne mainly by USDA.

With leadership from Dan Badger, chairman, the Literature Retrieval Committee continues to be one of our most active components. The committee sponsored a Literature Retrieval Workshop in May at the University of Missouri. Such workshops are critical to generate effective use of the automated literature search system, and more are being planned. Request a computerized search of your publications or a professional topic of your choosing—you will be impressed!

The work of the Postwar Literature Review Committee is winding down. Chairman Emerson Babb indicates final volume 4 will be published in early 1982. A special offer of all four volumes will be made to the AAEA membership.

J. B. Wyckoff heads a committee to provide travel grants to the conference of the International Association of Agricultural Economists meeting in Jakarta, Indonesia next year. The Executive Board allocated $7,500 of AAEA funds to support the grants.

Anticipating that funding of agricultural economics (including data systems) would be the major concern of Association members this year, I appointed a blue ribbon ad hoc committee last fall with Bud Stanton as chairman to explore this issue in depth and report to the Association. Some interesting results are presented in a general session Wednesday morning, to be published in the December *AJAE*.

The Association is in an excellent position to express its views on matters of funding, data systems, and other concerns through membership in the Federation of Scientific Agricultural Societies (Tweeten and Emery Castle representing AAEA), Federal Statistics Users' Conference (Norman Coats, representative), Committee of Professional Associations on Federal Statistics (Bruce Gardner and Glenn Nelson, representatives) and by liaison with the Census Advisory Committee on Agricultural Statistics (Bruce Gardner, representative) and National Bureau of Economic Research (Ed Schuh, representative).

I am deeply grateful to the Executive Board, committee chairpersons, and to all of you for giving me one of the most rewarding year's of my life. It is an exhilarating experience to work with such fine people. You provide a model of competence, dedication, and cooperation that I will always cherish.

Luther Tweeten, President

Report of the Secretary-Treasurer

The AAEA membership for 1980 was 5,845 (table 1). There was a reduction in virtually every category. The circumstances relating to the change in the secretary-treasurer's office can be blamed for this reduction which I hope will be temporary.

The number of members who paid their dues for 1981 on or before 1 April, and therefore received a ballot to vote, decreased by 102, and 197 fewer ballots were returned as compared to last year (table 2).

The 1980 operating statement for AAEA showed

Table 1. Number of Members and Subscribers, 1980, with Comparisons

Category	1978	1979	1980
Institutional members	32	34	32
Regular members			
U.S.	2,884	2,865	2,691
Foreign	811	870	555
Senior members[a]	137	140	121
Junior members			
U.S.	462	500	493
Foreign	47	52	50
Corresponding[b]			
U.S.	0	0	0
Foreign	0	0	0
Libraries & business			
U.S.	670	739	721
Foreign	1,271	1,335	1,179
Exchange	3	3	3
Total	6,317	6,538	5,845

[a] New, category established in 1976.
[b] Category combined with regular members in 1976.

a drastic change as compared with 1979 and previous years (table 3). It showed a negative balance of $6,502.85. Caution should be noted constantly in analyzing operating statements. Extraordinary items often convey normal activity. For 1980, we had $73,096.42 less income, including $14,199.38 less in dues and subscriptions, $19,624.50 less in page charges and reprints, and $12,119.50 less in *Journal* sales; but we had $13,116.50 increase in investment earnings, largely because of our bonds

Table 2. Number of Members Paid by 1 April, Ballots Mailed and Returned, with Comparisons

Category	1979	1980	1981
U.S. members	2,955	3,192	3,101
Canadian members	154	195	180
Foreign members	535	505	509
Total ballots mailed	3,644	3,892	3,790
Total ballots returned	1,804	1,871	1,674

and money mart funds. The miscellaneous income was $3,250 collected for industry banquet and $24.85 from exchange fees.

At the same time our income decreased, our expenses increased by $48,005.14. We paid $98,400.21 for five issues in 1980 as compared to $113,359.12 for seven issues in 1979, a reduced outlay of nearly $15,000. Most of the expense items ran about as in the past, except for three major categories: (*a*) editorial support, (*b*) subsidy to University of Minnesota Press, and (*c*) miscellaneous expense, of which two-thirds of the increase were due to moving the office. Not all of the moving allocation was spent.

The editorial support increased by $20,870 to $45,370. The practice has been to pay one-half of a year's support to the new institution assuming the editorship. The documentation center allocation was increased by $2,000 to $17,000. The University of Minnesota Press was paid a $10,000 subsidy for publishing volume 3, which, along with the remit-

tance of book sales, made this item $10,597.50. Almost all of the increase in the purchase of journals went to purchase two complete sets, on which we should double our money. The increase in annual meeting cost was largely because AAEA assumed the loss incurred at the University of Illinois in 1980.

The $31,006.14 miscellaneous expense category contained the following items: $800 for contract labor; $407.00 refunds due to overpaying; $15 345.00 to Iowa State, which included $345 paid for labor in packing and loading ($15,000 to ISU); $40 00 for post office permit; $69.15 for repairs; $2,000.00 to COPFAS; $7,052.98 for evaluation report (to be offset by a grant); $300 dues to Federal Statistics Users Committee; $3,059.34 for industry affairs banquet (offset by $3,350 income): $955.27 for liability insurance for directors; $899.40 for CPT maintenance contract; $29.00 for CPT fire insurance; and $50.00 for copyright of the issues printed.

Two very important facts stand out in the man-

agement of the AAEA activities. The AAEA can never relax on its efforts to collect dues, subscriptions, page charges, etc., and to enhance other income-producing activities, such as sales journals, advertising, address labels, etc. Second, the AAEA must carefully watch and control its expenditures. It is easy to finance a lot of good activities but are they worth the cost? Unless these things are carefully monitored, dues must increase substantially. It may be too costly to the profession to know the price elasticity of demand for AAEA services.

The National Registry projects started in 1973 with a grant from the U.S. Department of Labor. It was renewed or modified in June 1980 for the thirteenth time and was due to expire again 30 June 1981. We ended the year with a negative balance of $50.54 (table 4). Upon completion of the activities, including the final report, additional funds from the $10,404 held back by USDL should be forthcoming to cover the actual costs incurred.

In accordance with the policy established in 1973, the editor provided an income-expense statement for editorial support for 1980. It is incorporated as a part of this report (table 5). Since 1980 was a year of change of editors, Rhodes gave a report for his tenure, 1977–80, while Houck's report covered only the 1980 transition.

The balance sheet for 1980 showed a slight decrease ($6,502.85) in net worth, as compared to a $114,600.71 increase in 1979 (table 6). The AAEA assets are carried on the books at cost. However, market values are shown for your information. A problem has developed over the past two years with accounts receivable. It appears that our debtors are not in any big hurry to pay the AAEA. Perhaps we should consider adding a 1.5% monthly charge on all accounts thirty days past due.

This is my eleventh and last annual report. The Association is still healthy, viable, and active. With inflation and pressures for greater financial support for more and more activities, our fiscal strength can be sapped rather quickly. It has been a pleasure and certainly a great experience to have been your secretary-treasurer for the past eleven years.

John C. Redman, secretary-treasurer
31 December 1980

Investment Report

The portfolio subcommittee of the Finance Committee made a few changes in our portfolio during 1980. Our investments produced an income of $41,905.45 from all sources (table 1). We kept a large proportion in money mart funds, and the high interest rates were very kind to us. The $41,905.45 return was a 45.6% increase over 1979 and 149.8% over 1978. All assets, carried on the books at a cost of $342,472.40, had a market value of $448,977.26 at the end of the year. A large part of our portfolio was near cash. The detail on our stocks—the issue, amount, cost, dividends, market value, sales and purchases—is shown in table 2, and the detail on

our bonds is shown in table 3. I used the money mart fund heavily to earn a high rate of return on funds not needed for immediate payment of bills.

The portfolio subcommittee of 1980 (John Brake, Richard Feltner, and myself) tried to serve you well. With 1980, my eleven years as either chairman or member of the investment (portfolio) committee came to a close. I learned much.

John C. Redman
31 December 1980

Report of the Finance Committee

This annual report covers the activities of the Finance Committee for the period August 1980–July 1981. The primary activities during this period were to monitor AAEA income and expenses with special reference to issues relating to transferring the secretary-treasurer's office from the University of Kentucky to Iowa State University, provide guidance to the investment subcommittee, and prepare the 1982 budget. Members of the committee are

John A. Hopkin, chairman (Texas A&M University), Richard Heifner (AMS/USDA), John R. Brake (Cornell University), Richard Feltner (Louisville, KY), John C. Redman (University of Kentucky); and Sydney James (Iowa State University). The committee has not met formally during the year. However, they have been in communication via correspondence and telephone.

AAEA Financial Condition

Because the secretary-treasurer's office was in the process of transfer during the period November-January, the Finance Committee was unable to submit a coordinated report of Association income and expenses at the 1980 Board meeting in December. However, completed statements of expenses and income for 1980 have been included as tables 1 and 2 of this report. Additionally, the year-end balance sheet has been reviewed and is included in the secretary-treasurer's report. These tables indicate that the Association is in a healthy financial condition. Although expenses exceeded income by about $6,500 to 1980, this net loss was somewhat less than projected. Three items primarily account for the increased expenses from previous years: a $12,000 cost for transferring the editorial office, a $15,000 allocation for transferring the secretary-treasurer's office and the jump in the cost for editorial support from $28,000 to $45,370. The net worth of the Association (at market value of assets) on 31 December 1980 reached an all-time high of about $47,000.

Revised budget projections for 1981 are that income will exceed expenditures by $17,400. This projection recognizes increased earnings and capital gains on investments and anticipated collection of $25,000 in accounts receivable, as well as a strong reversal of a downtrend in membership dues experienced in 1980. However, because of costs associated with the printing of the handbook-directory, a net loss of $31,800 is projected for 1982.

In conclusion, the Association is in a strong financial position, with an investment portfolio of 1.3 times its projected annual operating expenses. Therefore, the Finance Committee recommends that there be no increase in membership dues at this time.

Financial Transfer of Association Books

As of 28 July 1981, the books of the association are in the hands of John Redman at Lexington, Kentucky. Immediately on completion of an audit by

the IRS of the 1979 accounts, all record books are to be transferred to Iowa State University, and the accounts at the University of Kentucky will be closed, except for a balance of $100 which will remain at the University of Kentucky to cover costs of forwarding *Journals* and other non-first-class mail that should be forwarded.

Special thanks are due to both Dr. John Redman, University of Kentucky and to Dr. Sydney James and Wesley Ebert, Iowa State University, for going the extra mile in effecting the transfer of the secretary-treasurer's office with a minimum of strain and disruption to the Association.

John A. Hopkin, chairperson

Report of Tellers Committee

Ballots received from AAEA secretary-treasurer were counted in accordance with the bylaws of the Association to preserve secrecy. A total of 1,674 ballots were cast. Leo Polopolus is the new president-elect. New directors are J. B. Wyckoff and Joseph Havlicek, Jr.

We suggest that the board of directors of AAEA investigate the possibility of using pencil-marked computer cards as the response mechanism for next year's election.

Roger A. Dahlgran
Roger Ginder

Report of the Editor

The transfer of the editorial office from the University of Missouri to the University of Minnesota proceeded smoothly. It began 1 May 1980. Much of the credit for this easy transition goes to former editor V. James Rhodes and former *AJAE* secretary, Donna Taylor. They were most helpful and cooperative at every step. Having the *Journal*'s assistant editor, Martha Luzader, continue in that position by moving to St. Paul was another major factor easing the process.

The Minnesota editorial office is well-served by its new secretary, Mary Strait. Associate editors Benjamin Senauer and Frank Smith have assumed their duties with vigor and professional skill. All of us in the editorial office are pleased with the encouragement and general support provided by the Department of Agricultural and Applied Economics and the University of Minnesota.

AJAE Operations

In the 12-month period 1 July 1980 to 30 June 1981, 342 new manuscript submissions were received. This appears to be a new record, up 3% from the 333 received during the same period in 1979/80. New submissions arrive at a steady rate of 26–30 per month, with no noticeable seasonality.

In 1981, the *Journal* will publish 96 refereed articles, notes, and comments in four quarterly issues and 70 papers and discussions in the May and December proceedings issues. In addition, Ronald Schrimper, the new book review editor at North Carolina State University, will provide 33 new book reviews. All of this will cover about 1,150 *Journal* pages.

At any one time, about 80–100 *Journal* manuscripts are out for review, continually engaging 150–200 referees, many of whom are not AAEA members. We are amazed at the cooperation, insight, professional commitment, and promptness of almost all *AJAE* reviewers. To each of the 535 listed in the accompanying table, we extend sincere appreciation. We also acknowledge with thanks the individual and collective contributions of the *Journal*'s 16-member Editorial Council whose names appear on the inside front cover of each issue.

Our relations with Heffernan Press have been most satisfactory this year. Heffernan has cooperated well in the editorial transfer, continuing to provide a high quality product and good service.

AAEA Newsletter

We will maintain the bimonthly *Newsletter* schedule. Because there is usually plenty of material to be published, the 16-page format will continue to be our standard. Currently, the *Newsletter* is being printed and mailed in a timely way by Bolger Printing Company of St. Paul, MN, using computerized mailing labels provided by the AAEA secretary-treasurer's office.

Former editor Rhodes deserves much credit and the membership's gratitude for bringing the *Newsletter* to life in 1979. It was clearly an immediate success, filling an obvious gap in the Association's service to its members. We intend to continue in the tradition he established.

Secretary-Treasurer's Office

The transfer of the secretary-treasurer's office from the University of Kentucky to Iowa State University could have been troublesome for *Journal* and *Newsletter* operations. However, the move was handled so skillfully by John Redman, Sydney James, and their respective colleagues that scarcely a beat was missed in providing financial support, mailing labels, and other services to the *Journal* and *Newsletter*.

We look forward to another year of publishing a strong, broad-gauged *Journal* and a lively, useful *Newsletter*.

James P. Houck, editor

Report of the Awards Committee

Special Award

John C. Redman, University of Kentucky.

Distinguished Extension Programs

Individual. **Richard L. Barrows,** University of Wisconsin.
Group. **Gerald A. Doeksen** and **James R. Nelson,** Oklahoma State University.

Distinguished Policy Contribution

Robert G. F. Spitze, University of Illinois.

Distinguished Undergraduate Teaching

Less than ten years' experience. **Kenneth L. Casavant,** Washington State University.
More than ten years' experience. **W. David Downey,** Purdue University.

Publication of Enduring Quality

Marion Clawson, *Methods of Measuring the Demand for and Value of Outdoor Recreation.* Washington, D.C.: Resources for the Future, 1959.

Outstanding Journal Article

William G. Tomek, "Price Behavior on a Declining Terminal Market." *Amer. J. Agr. Econ.* 62(1980):434–44.

Quality of Communication

Arley D. Waldo, Carole B. Yoho, Norbert A. Dorow, Thomas Ostenson, B. L. Flinchbaugh, and **Everett Peterson.** "Property Taxes—Reform, Relief, Repeal?" N. Cent. Reg. Extens. Pub. No. 39 and Minnesota Agr. Extens. Bull. 447, 1980.
Harold G. Halcrow. *Economics of Agriculture.* New York: McGraw-Hill Book Co., 1980.
Honorable Mention. Philip M. Raup. "Competition for Land and the Future of American Agriculture." *The Future of American Agriculture as a Strategic Resource,* ed. Sandra S. Batie and Robert G. Healy. Washington, D.C.: The Conservation Foundation, 1980.
Honorable Mention. Robert G. F. Spitze, Marshall A. Martin, Milton C. Hallberg, Tom A. Stucker, Alex F. McCalla, Bruce Gardner, Willard W. Cochrane, and **Sylvia Lane.** *Analysis of Food and Agricultural Policies for the Eighties,* ed. R. G. F. Spitze and M. A. Martin. North Cent. Reg. Res. Pub. No. 271 and Ill. Bull. 764, Nov. 1980.

Quality of Research Development

Oscar R. Burt, Won W. Koo, and **Norman J. Dudley.** "Optimal Stochastic Control of U.S. Wheat Stocks and Exports." *Amer. J. Agr. Econ.* 62(1980):172–87.
LeRoy Blakeslee. *Post World War II Government Policy Impacts on the U.S. Wheat Sector.* College of Agriculture Res. Cent. Tech. Bull. No. 93, Washington State University, 1980.
Honorable Mention. Richard E. Just and **Wen S. Chern.** "Tomatoes Technology and Oligopsony." *Bell J. Econ.* 11(1980):584–602.
Honorable Mention. Alan Randall and **John R. Stoll.** *Economic Surplus and Benefit-Cost Analysis.* Dep. Agr. Econ. AER Rep. No. 35, University of Kentucky, Oct. 1980.

Outstanding Ph.D. Thesis

Christopher Douglas Easter. "Supply Response with Stochastic Technology in Australia's Rural Export Industries." University of California-Davis (Quirino Paris, adviser).
Frederick Ian Johnson. "An Analysis of Brazil's Sugar Program, 1953–1975." University of Minnesota (Anne Krueger, adviser).
John Raymond Stoll. "The Valuation of Hunting and Related Amenities: A Conceptual and Empirical Approach." University of Kentucky (Alan Randall, adviser).

Honorable Mention (Ph.D. Thesis)

Saleh Halwan Humaidan. "Policies and Management Guidelines for Optimum Resource Utilization at Al-Hasa Irrigation and Drainage Project, Saudi Arabia." Oklahoma State University (Dean F. Schreiner, adviser).
Richard Mathew Klemme. "An Economic Analysis of the On-Farm Grain-Handling Decision Problem." Purdue University (David A. Bessler and Bruce A. McCarl, advisers).
Glenn Darwin Pederson. "A Conceptualization and Analysis of the Distributional Impacts of Alternative Agricultural Credit Policies." Michigan State University (John R. Brake, adviser).

Outstanding Master's Thesis

Richard Clay Barnett. "The Relationship between Domestic and International Liquidity and Nominal Agricultural Prices: A Time-Series Analysis." Purdue University (David A. Bessler and Robert L. Thompson, advisers).
Randall Ray Rucker. "The Dynamics of Montana Beef Cattle Inventories." Montana State University (Oscar R. Burt, adviser).
Ralph Semprevio. "Estimation of Economic Structural Parameters and Multipliers under Conditions of Multicollinearity in Simultaneous Systems." Virginia Polytechnic Institute and State University (Oral Capps, Jr., adviser).
Honorable Mention: Otto John Loewer. "The Economic Potential of On-Farm Biomass Gasification for Corn Drying." Michigan State University (Roy Black, adviser).

Honorable Mention: Abu Baker Bin Man. "An Econometric Analysis of the World Natural Rubber Market." Cornell University (David Blandford, adviser).

Honorable Mention: James Biklen Pendleton. "Allocation and Technical Efficiency of Traditional Agriculture in Northern Nigeria." Kansas State University (David W. Norman, adviser).

Honorable Mention: Robert M. Schoening. "Real Property Assessment Equalization and Preferential Assessment of Missouri's Agricultural Land: Effects on the Tax Incidence of Real Property Categories." University of Missouri (David Ervin, adviser).

Honorable Mention: Randolph Michael Sokal. "The Economic Effects of an Alternative to the Statutory Grain Freight Rates." University of Manitoba (E. W. Tyrchniewicz, adviser).

Honorable Mention: Yves Surry. "An Econometric Study of Future Trends in Demand for Soybeans and Soybean Products in France." University of Guelph (Karl Meilke, adviser).

Anne E. Peck, chairperson

Minutes

Minutes of the Executive Board Meeting, St. Louis, Missouri

The Executive Board acting as a program committee met in an informal session on 9 December 1980 at 8:00 p.m. to discuss the program for the 1981 meeting to be held at Clemson University.

The official meeting of the Executive Board was called to order by President Tweeten at 8:30 a.m. on 10 December 1980.

Present: Voting members:
Tweeten, Brown, Dennis, Heifner, Hopkin, Martin, Harl, King, Schuh

Members ex officio:
Koch Redman

Guests:
James (secretary-treasurer designate), Houck (editor designate), Pittman, Ikerd, Coats

1. Tweeten reviewed the agenda and obtained approval by general consensus.

2. Redman presented the minutes with corrections of the previously circulated copies of the 26–27 July 1980 meeting held at Urbana, Illinois. Brown moved the approval as corrected. Seconded. Passed.

3. Redman gave a preliminary report on the financial condition. The books will not be closed until 31 December, but reported that dues collection was down and payments on accounts due were slow. There appears to be a loss of about $1,650 on the annual meeting at Urbana. Hopkin moved that AAEA support the secretary-treasurer's assistant for one month and hopefully not more than two months for the purpose of closing the office smoothly at Kentucky. Seconded. Passed.

4. James, secretary-treasurer designate, reported that computerization of membership records was progressing nicely and that additional equipment was needed for the office. Hopkin moved that Iowa State University be authorized to purchase for AAEA suitable dictating and transcribing equipment. Seconded. Passed.

5. Hopkin reported for the Finance Committee. The portfolio subcommittee requested a reconfirmation of the authority by the Finance Committee to buy or sell equities up to 15% of the value of common stock in the portfolio without prior Executive Board approval. The Board clarified that the 15% limit was for the interval between Board meetings. Schuh suggested that the budgets for the past five years be prepared in "real terms" and that portfolio values be adjusted to reflect "real values" by using some acceptable index. No action was taken.

6. Schuh moved that the fidelity bond for the incoming secretary-treasurer be set at $100,000 and each secretarial assistant be at $10,000. Seconded. Passed.

7. Tweeten presented the report for Rhodes as outgoing editor.

8. Houck, as incoming editor, reviewed his plans and concerns and recommended that AAEA pay $200 as moving expenses for Martha Luzader. Hopkin moved that AAEA rèimburse Martha Luzader approximately $200 for moving expenses. Seconded. Passed.

9. Pittman reported on the activities being planned for the 1981 annual meeting at Clemson. Hopkin moved that the Clemson planning group be authorized to invite commercial concerns to have exhibits on a cost plus a fee schedule. Seconded. Passed. The secretary-treasurer is to provide mailing labels for mailing the meeting materials.

Hopkin moved that AAEA guarantee actual losses to Clemson University up to a limit equal to the difference between actual registration of members and 1,000 members times $30; and that Clemson and AAEA share in any surplus on a 50-50 basis. Seconded. Passed.

10. Ikerd presented comments on the role of the extension economist in the agricultural economics profession and in the AAEA. He expressed concern that extension economists do not have equal opportunity for publication in *AJAE* or as contributed papers at the annual meetings. The primary concern has been with research. The following proposals were specifically made:

(*a*) to include an economist with extension responsibility as one of the responders in all invited papers sessions at AAEA annual meetings;

(*b*) to identify selected papers sessions and organized symposia at the AAEA annual meetings with a rank order identification of potential interest with respect to research, extension, teaching, and industry members;

(*c*) to utilize the last half day of the AAEA annual meetings as meetings of the various segments within the association; research, teaching, extension, and industry;

(*d*) to require that the three top extension programs selected by the AAEA awards committee be shared with the other extension members of the AAEA;

(*e*) to include presentation of the top three extension programs in each category (group and individual) as a part of the AAEA annual meeting.

11. Hopkin moved that AAEA endorse in princi-

ple the cosponsorship of a symposium on "The Role of Professional Economists in Policy Work." Final approval will be subject to the endorsement of the AAEA Professional Activities Committee and the approval by a majority of the Executive Board when the program is developed. Seconded. Passed.

12. Coats reported on Federal Statistics Users Conference, indicating that AAEA would continue to support the FSUC and continue with the contacts already established.

13. The AAEA Membership Committee expressed interest in cross-checking names of members with the regional associations with the view of increasing membership of all associations.

14. Harl reported for the Resident Instruction Committee. He listed goals as follows: (*a*) obtain approval of a revised student section constitution and proposed revisions to AAEA Bylaws to implement changes; (*b*) revise the brochure "Economists in Agriculture, Business, Government, and Rural Affairs"; (*c*) develop an annual teaching workshop program; (*d*) promote student papers at the annual meetings; and (*e*) promote undergraduate student involvement in AAEA activities.

King reviewed the revised draft on the Student Section of AAEA Bylaws (Article XIII) and the proposed national constitution of the Student Section, American Agricultural Economics Association. Harl moved the approval of the revised section of the AAEA Bylaws (Article XIII) and the proposed constitution of the Student Section of AAEA. Seconded. Passed.

King moved that the proposal to revise the brochure be negotiated with Iowa State University as proposed. Seconded. Passed.

Harl led the discussion on developing a symposium or workshop on resident instruction and will convey to the committee the general sentiment of the Board to encourage the development of workshops.

There was a favorable reaction to the suggestion that the student chapters should receive the AAEA Newsletter as an encouragement of a greater involvement in AAEA activities.

Note: Because Redman had to leave early, James took the minutes that follow.

15. Dennis reported for the Industry Affairs Committee. He suggested a symposium around the subject "Embargoes Evaluated." It was decided that the industry group could handle the $100 honorarium needed for the banquet speaker at the annual meetings. This committee has a high priority goal of increasing the number of members. They request that the annual dues reminders go out earlier along with regular members.

16. It was moved by Schuh that the following committees be made standing: Extension, International, Industry, and Nominating. Seconded. Passed.

17. It was suggested that financial grants be sought now for the International Association of Agricultural Economists meeting in Jakarta, Indonesia, August-September 1982. It was moved by Schuh that the president appoint a committee on travel grants. Seconded. Passed.

18. James reported for the Handbook-Directory Committee. They recommend that the Association make maximum use of the Registry of Agricultural Economists (RAE) data base to produce the 1982 issue; that the new form being developed by Illinois State Employment Service (ISES) to collect RAE information be used in a joint effort, that the Board take action to encourage members to register for the RAE and the president prepare a letter to accompany the mailing to members; and that the *Handbook-Directory* contain name, address/telephone, rank or title, current employer, previous employer (three), nature of current employment activity, field of specialization, education, year of birth, citizenship, and current interest or research. It was moved, seconded, and passed that AAEA cooperate with RAE in the above outlined manner.

19. The work of the Publication of Postwar Literature Review Committee is winding down. Volume 3 will soon be off the press and volume 4 is in progress.

20. The Status of Blacks Committee is moving with deliberate speed. They are obtaining a membership list. There is a need to encourage more blacks into the profession, but a data base is needed first.

21. Tweeten discussed the Federation of Scientific Agricultural Societies (FSAS). The purpose of FSAS is to provide a forum for interdisciplinary communication and to enhance the capability of scientific agricultural societies to speak in a unified voice, re, national goals and priorities related to education and research; advise and counsel on public policy; assist colleges and universities in efforts to maintain and strengthen programs in research, teaching, and extension. King moved support and it was seconded and passed. King moved that Castle be asked to represent AAEA at the 17 February meeting. Seconded. Passed.

22. Considerable time was spent in developing the framework and identifying individuals for the invited papers section of the annual meeting. Also much discussion went into the consideration of and selection of nominees to forward to the Fellows Selection Committee.

23. Meeting adjourned.

Respectfully submitted,
John C. Redman, secretary-treasurer
Sydney James, secretary-treasurer (designate)

Minutes of the Executive Board Meeting, Clemson University

The meeting was called to order by President Tweeten at 8:30 a.m., 25 July 1981.

Present: Voting members:
Tweeten, Schuh, King, Brown, Hopkin, Dennis, Harl, Heifner, Martin

Members ex officio:
Ebert, Houck, James, Polopolus, Wyckoff, Havlicek

Guests:
Babb, Badger, Beattie, Bevins, Cordes, Eddleman, Evans, Faris, Fienup, Harris, Ikerd, Lewis, Peck, Robinson, Stanton, and various other committee members and reporting individuals

1. Harl moved the adoption of the agenda as prepared by Tweeten. Seconded. Passed.

2. Local arrangements for the following annual meeting were reviewed by Robinson and Faris. The goal of 1,000 registrants had been reached. There were no apparent problems. A dinner with the local staff, board members, and spouses was announced.

3. Tweeten reported the results of the election with Polopolus, president-elect, and Havlicek and Wyckoff replacing Brown and Hopkin as directors. The secretary-treasurer was granted permission to work with next year's Teller Committee in computerizing the counting of ballots.

4. The December 1980 minutes of the Board were presented and approved as amended by the following addition. It was moved by Schuh that the specific proposals made by the Extension Affairs Committee be detailed. Seconded. Passed.

5. James and Ebert reported on the status and condition of the business office. They reported that the move from Kentucky went smoothly with good cooperation. Space of one large room and one small office seems adequate and most refiling has been accomplished. Needed equipment has been purchased. The CPT word-processor is a much used item which simplifies office operations.

Much effort has been spent in computerizing membership and subscription name and address lists. This is now complete and a new program has been written which will incorporate *Handbook-Directory* information. Biographical data from the Employment Registry will be transferred early this fall. Additionally, the new program will contain personal information and data useful to the president and directors for management purposes.

A new liability insurance policy for the Association has been purchased and the office staff are all bonded. Dougherty & Company, certified public accountants, have been engaged to perform the annual audit. They will prepare the required federal tax forms.

The Western and Northeastern Associations were pleased with the joint dues billing for 1981. The Western Association increased their membership by about 200. Both wished to continue that service. Tweeten expressed the need for reciprocal arrangements. This met with Board approval.

The following motions followed the secretary-treasurer's report:

(*a*) Schuh moved "that a new class of membership be activated to be known as family membership for the spouse of a regular member and additional family members who are under the age of 18 and who are members of the family of the regular member. The dues per family membership shall be $12.50 per person per year. Individuals holding family membership shall not be entitled to receive, as part of membership in the Association, copies of the *Journal* or *Newsletter*." Seconded. Passed.

(*b*) Hopkin moved "that the maximum period of student membership be increased from 3 to 5 years." Seconded. Passed.

(*c*) Schuh moved "that beginning with 1982 dues, foreign memberships and subscriptions (outside of the U.S., Canada, and Mexico) be assessed $4 to cover additional mailing and handling fees instead of the current $2 charge." Seconded. Passed.

(*d*) Schuh moved "that the fee to back-order issues of the *Journal* be increased from $1 to $2 for those who pay dues later than January 15." Seconded. Passed.

6. Hopkin reported for the Finance Committee. The detail of budgets and receipts and expenses appear as a separate report. The 1981 budget and year-to-date accounting figures were reviewed. The 1982 budget was presented. After adjusting the 1982 budget for changes caused by Board action, it was approved by the Board. A $17,400 surplus is budgeted for 1981 following a $6,499 deficit in 1980. The projected deficit in 1982 is estimated to be $31,800. This is the approximate cost of printing the *Handbook-Directory*. It was moved by Hopkin, seconded and passed, "that there not be an increase in dues in 1982. This deficit would be covered from stock investments of the Association.

The Portfolio Subcommittee reported selling Browning-Ferris stock which had doubled its value in one year. Profits from this sale plus money-market investments were used to purchase four new stocks for a total of about $34,000. The total current value of the portfolio is near $511,400 consisting of $278,000 stocks, $94,600 bonds, and $138,000 money-market assets. Harl moved adoption of the revised 1981 budget. Seconded. Passed. Hopkin moved adoption of the 1982 budget. Seconded and passed after revision incorporating other Board action.

7. Hopkin reported that the Ad hoc Transfer Committee had finished its work with the move of the business office to Ames, Iowa, completed. There are some financial records and some funds still in Kentucky, but these will be transferred within a few weeks. The 1980 audit has been finished and the 1979 IRS tax audit will soon be completed.

Schuh moved "that the Transfer Committee be dissolved with a vote of thanks." Seconded. Passed.

Hopkin moved "that $100 be left in Kentucky for use by John Redman for postage and miscellaneous expenses." Seconded. Passed.

8. Houck reported on the condition and situation of the editorial office. The transfer from Missouri to Minnesota proceeded very smoothly. There was good cooperation by all. He was pleased with the four-up labels and computerization of names and addresses. Mailing has gone very well.

During the past 12 months 342 new manuscript submissions were received—a record number. In 1981 the *Journal* will publish 96 refereed articles, notes, and comments. At any one time there are 80–100 manuscripts out for review engaging 150–200 referees.

Bimonthly issues of the *Newsletter* will continue in 1982 under the current format. It is being printed by Bolger Printing Company of St. Paul, MN. There may be need in some future period to separate the *Newsletter* editor from the *Journal* editor. The functions and operations are such as to make this feasible. The *Newsletter* editor could do some things that the current editor does not have time for.

Havlicek will need to be replaced on the Editorial Board because of his recent election as director.

The difficulty of assigning page charges to proceedings issues was discussed. It was moved by Harl "that no charge be levied on the president's address, fellow's lecture, and invited addresses. All other papers presented would be assessed a page charge fee the same as for other issues of the *Journal*. Specific waivers can be granted by the editor with concurrence of the president. This policy applies equally to proceedings of the Allied Social Science Association." Seconded. Passed.

The large inventory of back issues of the *Journal* was discussed in detail. That inventory currently contains about 45,700 issues weighing about 18 tons and occupying 1,500 cubic feet of storage space. A graduated number was suggested for inventory control ranging from about 50 for older issues to 500 for more recent issues. Storage of these costs the Association about $1,000 per year. Harl moved "that the Association undertake during 1982 under the auspices and supervision of the secretary-treasurer of the Association, a campaign to provide an opportunity for individuals, firms, libraries, and others, to obtain copies of the *Journal*, published before 1980, at $2.50 per copy for North American purchasers and $3.00 per copy for other purchasers. The sale to be carried out on a first come, first served basis. Sales are to be discontinued whenever inventories fall below 75% of the levels suggested in the memorandum, "AJAE Inventory Policy dated 25 July 1981."

Considerable discussion centered around alternative forms for publishing the writings and work of Association members. A need was expressed in particular by the extension group but also included those in teaching and industry. Reference was to an earlier study of this matter appearing in vol. 60, no. 5 (Dec. 1978), pp. 1094–8, of the *Journal*. President Schuh will appoint another committee to again look at this matter. Concern was expressed by letter and in the Extension Committee report.

9. King by assignment presented a resolution supporting the establishment of a National Academy of Agricultural Sciences. King moved adoption and it was seconded and passed. The resolution will appear separately as part of the business meeting minutes. King presented a list of suggested changes which clarified the language of the proposed document to reflect and clarify economic issues and terms. The latter was to be presented to the writing team for their consideration.

10. Miscellaneous correspondence requiring Board attention was presented.

(*a*) The consensus was that the review process for material appearing in the Proceedings issue of the *Journal* need not be changed.

(*b*) Long survey questionnaires were an apparent difficulty for some. It was agreed that the secretary-treasurer should exercise discretion in providing mailing labels including a review of the questionnaire which could go to the president if further consideration were necessary.

11. Stanton reported for the Agricultural Economics Financial Resources Committee. Funding of agricultural economics research was thought to be one of the more serious matters. Uncertainty was expressed over ESS (ERS). Interference with the freedom of research was a concern. Some statistical series are being cut. It was agreed that this committee should continue and they should consider the possibilities for conducting a workshop including ESS, industry and academia to consider this matter in detail.

The CRIS system was discussed. It was felt that there were problems with the output not reflecting actually what was being done by economists.

12. Ikerd reported for Extension Affairs Committee. It was moved by Harl "that Affairs be removed from this title as well as for the Industry Affairs Committee." It was seconded and passed.

Appreciation was expressed for the invited papers session specifically to deal with extension delivery systems. Disappointment was expressed that the Board had not dealt with his proposals made at the December meeting.

Additional proposals dealt mainly with publication outlets for extension economists

(*a*) to change the editorial system of the *Journal* to include associate editors in research, extension, and teaching.

(*b*) to give serious consideration to dividing the "Notes" section of the *Journal* into separate Extension, Teaching, Research, and Industry parts.

Ikerd did not recommend a popular version of the *Journal* for the fear of ranking.

The Board deferred action on these and former proposals of this committee until more time could be devoted to their consideration. It was agreed that a new and separate committee should be ap-

pointed to study the publications of the Association as mentioned in item 8.

13. The report of the Membership Committee was accepted with appreciation. It was noted by James that memberships for 1981 was now about 200 above last December and should increase to about 300. Campus recruiters will be provided membership lists earlier in 1982 than in 1981.

14. Cordes reported for the Professional Activities Committee (PAC). Recommendations generated the following Board actions:

(*a*) Moved by Harl to cosponsor a Farm Foundation conference titled "Perspectives on Agricultural Food Policy Research." Seconded. Passed.

(*b*) Moved by Hopkin to cosponsor a USDA conference titled "The Economics of Food and Agricultural Trade," but not the publication of the proceedings in the *Journal*. Seconded. Passed.

(*c*) Moved by Dennis to cosponsor two conferences proposed by the American Society of Agricultural Engineers: "Second International Livestock Environment Symposium" and "International Conference on Plant and Vegetable Oils." Seconded. Passed.

(*d*) Moved by King not to give an award for "Excellence of Published Research in Economic Development." Seconded. Passed.

In addition seven issues were placed before the Board. These issues and actions follow:

(*a*) That the Association develop a policy of conduct for its officers while holding office. King moved the adoption of PAC's statement as follows:

> "It is the personal obligation and responsibility of individual board members, committee members, and officers to (1) avoid the misuse of the Association for the personal gain of oneself or others or (2) avoid involvement in decision-making activities that represent a conflict of interest with regard to AAEA. In situations of doubt, the individual is to apprise the Board of the situation, and ask for its counsel."

Seconded. Passed.

(*b*) That the Association look into additional services which could be provided its members. PAC was charged to retain this area of concern.

Written job descriptions for standing committees will be referred to President-elect Schuh for handling as he sees fit.

(*c*) Increasing the privileges associated with Association membership was thought to belong to PAC. Acceptance of Issue 3 without action was moved by Hopkin. Seconded. Passed.

(*d*) No official action was taken on Issue 4 relating to annual meeting content. In the December 1980 *Newsletter*, President Tweeten spelled out the procedure now in use for developing the program for annual meetings.

(*e*) The role of the 1890 Institutions was deferred until the Committee on Blacks reported.

(*f*) The policy analysis capabilities of the profession (Issue 6) was deferred to Stanton's committee on current policy issues.

(*g*) The need for AAEA policy guidelines was expressed. This involves the missions of the various committees. No Board action was taken, but Tweeten expressed willingness to survey those committees he appointed as a beginning for such a compilation.

15. Harris reported for the Resident Instruction Committee. The corrected Constitution for the SS-AAEA was distributed including Section XIII of the Bylaws. Harris presented a new career brochure and Harl moved its acceptance. King moved "that Agricultural Production, Marketing, Credit, Natural Resource and Rural Development be added under the main heading." Seconded. Passed. Wyckoff moved to add the word management. Seconded. Passed. Schuh moved "to include Policy." Seconded. Passed on a 4 to 3 vote. The original motion passed. The secretary-treasurer will advertise the new brochure and sell on a cost basis.

The committee expressed appreciation for the symposium "Dimensions in Teaching Agribusiness Management, Farm Management, and Agricultural Policy." Future plans call for a two- or three-day workshop in 1983.

16. The report of the Industry Affairs Committee was accepted with no Board action. A membership of 43 was noted The current method of invoicing was appreciated. They were pleased to have been given an opportunity to organize a symposium at the annual meeting entitled, "Embargoes Evaluated."

17. Fienup reported for the International Committee. It was noted that in separate action under the recommendation of Wyckoff, the Board had approved $7,500 in travel grants to the IAAE meetings in Indonesia in 1982. Requirements for obtaining a grant are (*a*) member of AAEA, (*b*) U.S. citizen, (*c*) under 36 years old, and (*d*) have an international dimension in their work.

The committee has used its time promoting seminars and workshops. The ADC/RTN workshop planned was not held because of a lack of funding. However, the International Committee did jointly sponsor a RTN seminar on "Food System Organization Problems in Developing Countries." They were pleased to have a place in the annual meetings. Report accepted.

18. The report of the Postwar Literature Review Committee was accepted. Babb noted that for volumes 1 and 2, $7,741 of royalties has been paid for 3,216 copies sold. To date, 319 copies of volume 3 have been sold.

19. The report of the Literature Retrieval Committee was given by Badger. The Board was encouraged to support the AAEDC at a level of $21,000 for next year (1 Oct. 1981 to 30 Sep. 1982). This support was moved by Schuh. Seconded. Passed.

Mention was made that University of Missouri has a complete cross-referenced *AJAE* file. This file is available through the Department of Agricultural Economics.

This committee offers its services to area associations and individual departments in conducting workshops demonstrating what is available and how to retrieve the information. Commercial vendors are willing participants of such workshops.

Plans are to publish a quarterly newsletter highlighting new agricultural economics and related files.

20. James reported the current status of the next *Handbook-Directory.* Approximately 2,200 Employment Registry forms have been returned, leaving a shortage of near 1,800 members. This information will be transferred by tape to Iowa State University to be read into the new computer membership file. A second survey of the membership using a simplified form was authorized with a deadline of 15 December for completion. The plan is for the biographical data collected to appear on the membership dues invoice for correction and update. Harl moved "that the letter "O" be used instead of "W" for the telephone code." Seconded. Passed.

Further, it was moved by Harl "that the Executive Board approve publication of a *Handbook-Directory* to include the information contained in the sample sheet distributed to the Board for examination and reaction and that the Handbook-Directory Committee review the sections of information included in the *Handbook-Directory* with encouragement to eliminate (*a*) those sections containing information published elsewhere, (*b*) those sections with low rates of perceived usage, and (*c*) those sections the inclusion of which will result in undue delay of publication of the *Handbook-Directory.*" Seconded. Passed.

21. The report of Professional Registries and Employment Committee was received but no action was taken. Johnson was pleased that there were about 1,645 agricultural economists listed in the Employment Registry who express interest in being considered for some type of employment. Illinois Job Service is satisfied with the performance and plans to continue the service. The committee will develop a new flyer explaining the services and purposes of the Professional Registry.

22. Lundeen reviewed the results from the survey conducted by the Status of Women Committee. Hopkin moved to recommend "that the Committee become a special Committee." Seconded. Passed.

23. Evans reported for the Status of Blacks Committee. He reviewed a questionnaire they were planning to use to study blacks in the profession. The proposal is now ready for funding. Several sources were suggested. Tweeten asked that he keep in mind the 1890 institutions in his study.

Harl moved "that the Board endorse the study of black and nonblack agricultural economists." Seconded. Passed.

The secretary-treasurer is to cooperate in furnishing name lists.

24. Lewis, acting head of the Department of Economics, Utah State University, reported plans for next year's meetings. This will be cosponsored by the Western Association. Beattie, president, expressed interest in jointly selecting the contributed papers and having a special session for the Western Association. They will publish their own proceedings.

Facilities were reported to be adequate to house the 1982 meetings.

Bevins, president of the Northeastern Association, requested that the 1984 meetings be held jointly at Cornell University. It was so moved by Schuh. Seconded. Passed.

25. Peck reported for the Awards Committee. This year's winners were presented. She was thanked for the excellent work she had done. Because of possible confusion over one person being selected to receive two similar awards, the following motion was moved by Harl, "If an article is selected to receive both the Outstanding *Journal* Article Award and Quality of Research Discovery or Quality of Communication Awards, the matter shall be resolved by the chair of the Awards Committee in consultation with the recipient or recipients involved." Seconded. Passed.

26. Schuh moved the following nominating committee for 1982 elections: Kenneth C. Clayton, Gerald L. Cole, George Lee, Alfred L. Parks, Joseph C. Purcell, J. William Uhrig, and Russell Yeomans. Seconded. Passed.

27. The next Board meeting was scheduled for 20, 21 November in St. Louis. There will also be a meeting 28 December in connection with the ASSA meetings in Washington, D.C.

28. In accordance with the Bylaws, the secretary-treasurer and editor were evaluated by the executive board with reappointment for next year.

29. Those board actions making changes in the Bylaws were reviewed by Harl with specific wording presented. These were moved, seconded, and passed.

Respectfully submitted,
Sydney C. James
Secretary-Treasurer

Minutes of the Annual Business Meeting, Clemson, South Carolina

The 70th annual business meeting was called to order by President Luther Tweeten on 28 July 1981 at 8:30 a.m.

1. Tweeten presented for approval the minutes of the previous annual business meeting held at Urbana, Illinois, 29 July 1980, as published in the Proceedings issue, of the *Journal,* December 1980, p. 1146. Seconded. Passed.

2. The results of the recent elections was announced with Leo Polopolus, president-elect, J.B. Wyckoff and Joseph Havlicek, Jr., directors. Each

of the Board members was individually recognized. Retiring Board members were thanked for the service they had rendered.

3. Tweeten reviewed items of interest and importance to the general membership from the past two meetings of the Board. The following items are detailed in the Board minutes: the need for additional biographical data to publish a good *Handbook-Directory*, family memberships, increasing the longevity of student memberships to five years, increased costs of postage and handling for foreign memberships to $4, increased cost for obtaining late membership back issues of the *Journal* to $2, selling of overinventoried issues of the *Journal* at mailing costs, the increase in membership since last December, the creation of a new careers brochure, travel grant to the IAAE meetings, support of AAEDC, and special thanks to all those who had worked so hard and willingly on committees and various assignments over the past year.

4. James reviewed the status of the Association business office. The move from Kentucky was made with full cooperation. The office is now operating smoothly with refiling nearly completed. Membership vouchers should go out on time this year. Computerization of membership records and *Handbook-Directory* information was reviewed. The business office is established to serve the membership.

5. Redman presented the 1980 financial report, which appears separately. He called attention to the fact that the operating statement was on a cash basis and year-end summaries would be expected to show some variations. The transfer of offices disrupted some operations and resulted in some additional expenses.

6. Hopkin distributed and discussed the annual budgets. He reported that the Association was financially healthy. He called attention to increasing editorial costs and to the transfer costs of both the secretary-treasurer's office and the editor's office. The balance of the financial accounts will be transferred from Kentucky to Iowa shortly. Budget data appear separately.

7. Tweeten read the auditor's report indicating that all financial accounts are in proper order.

8. Houck reported the condition of the editor's office. He reviewed the review process and magnitude of the operation.

9. Tweeten recommended the previous action of the Board to change the Extension Affairs Committee, Industry Affairs Committee, International Committee, and Nominating Committee from special committees to standing committees and to drop the word "Affairs" from the Extension and Industry Committees. It was moved, seconded, and passed.

10. The resolution prepared by King in support of the establishment of a National Academy of Agricultural Sciences was presented. It was moved, seconded, and passed. The text of this resolution appears separately.

11. A resolution of appreciation to Clemson University for hosting the 1981 annual meetings was presented by President-elect Polopolus. It was moved, seconded, and passed. The text of the resolution appears separately.

12. The schedule of upcoming meetings was reviewed:

Annual summer meetings;

1982	Utah State University, Logan, Utah
1983	Purdue University, West Lafayette, Indiana
1984	Cornell University, Ithaca, New York
1985	Iowa State University, Ames, Iowa
1986	Open

Allied Social Science Association, all scheduled to be held 28–30 December in their respective years:

1981	Washington, D.C.
1982	New York, New York
1983	San Francisco, California
1984	Dallas, Texas
1985	New York, New York

13. The new nominating committee was presented by incoming President Schuh. (Names appear in the minutes of the Board.) They were moved, seconded, and passed.

14. The presidency was conveyed from Tweeten to Schuh and he adjourned the meeting.

Respectfully submitted,
Sydney C. James
Secretary-Treasurer

Resolutions

In support of the establishment of a National Academy of Agricultural Sciences,

Whereas the National Academy of Sciences is "dedicated to the furtherance of science and its use in the general welfare," and

Whereas agriculture, engineering, and medicine constitute the three primary fields of applied science, and

Whereas a National Academy of Engineering and an Institute of Medicine are now established under the charter of the National Academy of Sciences, and

Whereas there is need for a recognized multidisciplinary body of competent and creditable scientists and scholars who may provide advice and counsel on national policies, issues, and programs to enhance the achievement of national and world agricultural goals,

Be it therefore resolved that The American Agricultural Economics Association (AAEA) hereby recommends that the United States establish a National Academy of Agricultural Sciences under the charter of the National Academy of Sciences to complement and assist the National Academy of Sciences, the National Academy of Engineering, and the Institute of Medicine in furthering science and the general welfare, in serving as advisor to

federal government, and in guiding the National Research Council. More specifically, the National Academy of Agricultural Sciences shall have as its purposes:

(*a*) to advise the federal government on agricultural production, distribution, and stewardship for future generations of the nation's agricultural and natural resources;

(*b*) to assess needs, identify priorities, and project goals for agricultural research and education;

(*c*) to foster interdisciplinary study and cooperation within the science community on national and global agricultural issues;

(*d*) to recognize scientists and scholars for outstanding contributions to the generation, integration, and application of knowledge in agriculture.

Further, that the Secretary of AAEA be directed to send copies of this resolution to the President of the National Academy of Sciences and the National Research Council and to representatives of organizations presently affiliated with the Federation of Scientific Agricultural Societies.

Adopted by the AAEA Executive Board on (25 July 1981) and approved by the membership of AAEA at its annual business meeting at Clemson University this 28th day of July, 1981.

Resolution

The officers, members, families, and guests of the American Agricultural Economics Association acknowledge the warm and cordial hospitality exhibited by the faculty and staff of Clemson University on the occasion of the annual meeting held on the Clemson University campus, 26–29 July 1981. Therefore,

Be it resolved that the American Agricultural Economics Association express its sincere gratitude to Dr. Bill Atchley, president of Clemson University, Dr. Ed Faris, head of the Department of Agricultural Economics and Rural Sociology, and Dr. Bob Robinson, chairman of the Steering Committee, Dr. Jerold Pittman, as well as the faculty, staff, students, and families of the Department of Agricultural Economics and Rural Sociology of Clemson University.

Be it further resolved that a copy of this Resolution be sent to President Atchley, Dr. Ed Faris, and Dr. Bob Robinson, plus copies to each member of the Steering Committee and others at Clemson University as deemed appropriate.

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to Sydney C. James, Secretary-Treasurer, American Agricultural Economics Association, Department of Economics, Iowa State University, Ames, Iowa 50011.
